# PRÓLOGO

*a la 1ª EDICIÓN (1914).*

---

Con el objeto de aportar algún esfuerzo de consideración tendente al adelanto de la hermosa ciencia del Ingeniero Constructor, emprendimos hace algunos años y hemos llevado á cabo, la traducción del inmejorable *Manual del Ingeniero* escrito en inglés por John C. Trautwine, de los E. E. U. U. de América, y convertido además todas sus fórmulas, tablas y ejemplos, que naturalmente trae dicho autor en sistema inglés, al sistema métrico.

Con este trabajo creemos haber llenado el gran vacío que dificulta, de modo notable, la práctica expedita y certera de los constructores Españoles é Hispano Americanos, por la falta de Manuales y Formularios verdaderamente prácticos, tanto por el criterio que los inspira como por el método y exposición de las reglas y fórmulas que han de usarse en los diversos y complejos casos que á diario se presentan al Ingeniero Constructor. Y son aquellas precisamente las cualidades que han dado al Trautwine el éxito y celebridad insólitos; éxito comprobado irrefutablemente por los (140 000) *ciento cuarenta mil ejemplares* que hasta ahora se han vendido de dicha obra.

Pero la culminante característica de este formulario está en el inmenso y laborioso acopio de resultados escogidos entre todos los innumerables trabajos de investigación experimental llevados á cabo en estos últimos

años por los más célebres Constructores y las más reputadas Asociaciones para extender sobre base firmísima la Construcción Moderna.

Además el Trautwine no solo supera á las obras análogas en español por la cantidad de materia que contiene, por lo adecuadas de sus fórmulas, por la sencillez y claridad, al alcance de técnicos y profanos, de su exposición, de sus diagramas y tablas, sino que es muy superior á todos los formularios franceses que son los más consultados por los Constructores Hispano Americanos. Otra de las ventajas que se derivan de la publicación de esta obra en español es sin duda que nos pone en relación, nos hace conocer los importantes y eficaces progresos de la ingeniería Norte-Americana é Inglesa y los admirables trabajos de sus corporaciones científicas, generalmente tan desconocidos para los Ingenieros y Constructores que hablan español, pues es muy sabido que una gran parte aprenden el francés pero muy pocos el inglés.

Como cada día se estrechan más las relaciones entre los Constructores é Ingenieros Ingleses é Hispano Americanos, ya que ambos idiomas van extendiéndose constantemente, y son muchas las obras y empresas en que trabajan juntos Ingenieros ingleses y españoles y más frecuentes aun los casos en que tenemos que hacer pedidos ó estudiar proyectos que nos obligan á conocer el sistema inglés en toda su amplitud, hemos dejado casi odas las fórmulas inglesas al lado de sus equivalentes métricas, lo que en nada estorba la lectura en el sistema métrico. Es éste quizás el unico texto de esta índole que contiene ambos sistemas.

Otra insuperable ventaja, en este Manual, es sin duda la de hacer que sus prácticos consejos, dictámenes y fórmulas vayan siempre precedidos de una exposición completa y sintética de toda la teoría que sirve á aquellos de fundamento, desarrollada en capítulos de una síntesis y claridad admirables que traen á la memoria los elementos indispensables para hacer conscientes y fecundas las aplicaciones de las fórmulas y los principios, dando al teórico el empirismo que le da iniciativa y éxito y al

empírico la teoría que le da la fé y la deliberación tan necesarias en el espíritu del Constructor.

Por no introducir alteraciones que podrían quizás desvirtuar una obra de tan notoria reputación y fama, no hemos ni siquiera modificado su estilo, aunque siempre claro y preciso, á veces quizás demasiado simple y llano.

El tipo de letra, la división y distribución de las materias, la numeración de los capítulos, párrafos, etc., todo es idéntico al texto inglés; y lo es de tal manera, que los Ingenieros que hablan inglés y poco el español y no conocen su terminología y viceversa, pueden estudiarla y aprenderla cotejando los capítulos de número á número y de renglón á renglón.

Hemos adoptado el práctico sistema de poner en letra gruesa al principio ó dentro del párrafo ó capítulo, la palabra ó frase más importante facilitando así la rápida consulta de una cuestión cualquiera.

También en el índice, como en todo lo demás, hemos seguido al autor que no copia siempre fielmente el título de los capítulos ó párrafos sino que solo menciona á veces la más importante de las materias tratadas en la página citada.

Los autores de esta obra se han consagrado con el mayor ahinco y laboriosidad á mejorar cada una de las ediciones sucesivas, á tal punto, que las primeras ediciones solo tenían como la mitad del contenido de esta última (19ª). Como seiscientas páginas de materia nueva y como doscientas revisadas y modificadas se encuentran en la última edición, resultado de unos 19 ó 20 capítulos nuevos agregados y otros tantos casi en u totalidad escritos de nuevo.

Nosotros en las 1272 páginas que forman la obra, hemos reemplazado solo unas diez ó doce páginas de materias por las razones que en debido lugar exponemos; hemos agregado algunas páginas con los más importantes problemas del trazado de curvas, del mismo autor, pues de otro modo quedaba incompleto el capítulo de « Ferrocarriles ». Sólo hemos suprimido los capítulos que tratan de Biblio-

grafía y en parte la lista de precios pues sólo tienen importancia para los Ingenieros Norteamericanos.

No se escapa á nuestros colegas las dificultades de diversa índole que hemos tenido que vencer, sobre todo en la adecuada elección de multitud de términos técnicos, llegando en muchos casos á tener que crearlos; puesto que el gran progreso alcanzado sobre todo en los Estados Unidos por las ciencias é industrias que se relacionan con el extensísimo Arte de Construir, ha hecho que multitud de sus términos y expresiones, no tengan aún su equivalente fijo en español.

ALBERTO SMITH.

---

NOTA IMPORTANTE :

Siguiendo el sistema del Autor, hemos adoptado *el punto*, para separar los números enteros de los decimales y la coma para separar los enteros entre sí.

# PRÓLOGO

DE LA

*SEGUNDA EDICIÓN* (3ª emisión) *traducida de la* (20ª) *última edición del texto Inglés.*

Despues de la magnífica acogida con que el pùblico ha recibido las dos emisiones de la primera edición de esta traducción, no hemos omitido esfuerzo ni gasto para traer a esta edición todas las mejoras de la última del texto inglés o sea la 20ª del año de 1919. Ademas nos hemos esmerado en la corrección de todas las erratas, inevitables en las primeras ediciones de obras tan complejas como esta y, como lo observará el lector, hemos mejorado, no solo la calidad del papel sino también la de la encuadernación, pasta, etc.

En efecto : la actual edición trae como 340 páginas nuevas, sobre todo en el ramo de ferrocariles, y 16 páginas sobre los principios y fórmulas del Derecho en relación con las prácticas de la Construccion, materia esta que no existe en el texto inglés ni que sepamos en ninguna otra, de la índole de esta obra, en los otros idiomas. Mas adelante exponemos los motivos que nos han inducido a esta innovación que juzgamos mui útil.

Volviendo al capítulo de ferrocarriles, haremos una sucinta comparación que dé al lector una idea de la mayor, de la mui grande, extensión dada a algunas materias y ademas de los capítulos enteramente nuevos que aparecen en esta edición :

| | PÁGINAS En la edición anterior. | Enesta edición. | |
|---|---|---|---|
| Via | 15 | 44 | |
| Desvios y Cruceros | 25 | 52 | |
| Curvas circulares | 20 | 93 | |
| Curvas en espiral | | 18 | Nuevo. |
| Señales | | 12 | Nuevo. |
| Estaciones y patios | 10 | 16 | |
| Materiel rodante | 10 | 17 | |
| Resistencia en los trenes | | 14 | Nuevo. |
| Dinámica de los trenes | | 11 | Nuevo. |
| Costo de explotación | | 14 | Nuevo. |
| Costo de construcción | | 14 | Nuevo. |
| El Derecho en relación con la Construcción | | 24 | Nuevo. |
| Páginas | 80 | 329 | |

Los mas nuevos y recientes procedimientos prácticos de la Ingenieria están en esta edición y sobre todo los preceptos y prácticas adoptados por la Asociación Americana de Ingenieros de Ferrocarriles (American Railway Engineering Association).

Aparecen nuevas tablas de : Radios de curvas con sus logaritmos; Cuerdas Largas; Ordenadas Medias y funciones de las curvas de (1°) un grado.

La discusión y práctica del replanteo de curvas es enteramente nuevo asi como el estudio y trazado de curvas Espirales, que es el recomendado por la ya citada A.A. de I. de F. Fíjese el lector en la importancia práctica de los también nuevos capítulos sobre Señales; Resistencia y Dinámica de los Trenes; Costo de Construcción y Explotación y el de los preceptos del Derecho en relación con la Construcción en general, tan util a los que dirigen obras.

En toda la parte nueva de esta obra, como en las anteriores ediciones han seguido sus autores el sistema de mantenerla por su claridad y fácil lenguaje al alcance, no solo de Técnicos é Ingenieros sino también de los jefes de trabajo, maestros de obras, etc., que posean simples elementos de Aritmética, Geometria, etc. Este ha sido el secreto del éxito incomparable de esta obra.

Como consecuencia de la introducción de mucha materia nueva y de las modificaciones y mejoras en muchos capítulos hemos tenido que cambiar el Indice aprovechando esta ocasión para hacerlo mucho mas minucioso.

Volviendo al capítulo sobre el Derecho y las construcciones observamos que los ingenieros y jefes de obras en el estudio y construcción de éstas, son quizás entre todos los profesionales los que mas necesitan conocer los preceptos del Derecho que se relacionan con el ejercicio de su profesión. Desde el emplazamiento de sus construcciones, durante la ejecución y luego en la explotación, están expuestos a vulnerar el derecho ajeno por la falta de conocimientos, siquiera generales y someros de aquellas prescripciones. Cuantos litigios han resultado de tales deficiencias!

Es por esto que hemos creido conducente y eficaz agregar en esta nueva edición las muy breves apuntaciones, excesivamente sintéticas, que ha tenido la bondad de suministrarnos el notable Jurisconsulto venezolano, Doctor José Loreto Arismendi, cuya ilustrada colaboración jurídica hemos solicitado y a quien reiteramos nuestra gratitud por su trabajo.

Los principios expuestos por el Doctor Arismendi están basados sobre el Derecho Francés, en atención a que éste es el que ha servido generalmente de modelo para calcar sus leyes las naciones de habla española.

Asi como, por la índole de este Manual, no se entra en razonamientos y conexiones extensos y constitutivos de un estudio completo de la técnica de la ingenieria, dando solo las fórmulas y la exposición sintética de las teorias y principios, asi también, en el apéndice juridico de que tratamos, sólo se formulan mui brevemente algunos dictámenes que, íntimamente ligados con las materias de esta obra, sirvan como de advertencia útiles para orientar y provocar consultas y más amplios estudios, cuando fuere necesario.

Suplicamos á todos nuestros bondadosos lectores nos excusen las faltas y errores que hayamos podido cometer y nos envíen por correo á la siguinte dirección: Alberto SMITH c/o TRAUTWINE C°, 257. S. 4th St — Philadelphia (Penn'a), todas las observaciones que crean pertinentes, contribuyendo así, con nosotros, al mejoramiento de la obra.

Paris, octubre 1921.

ALBERTO SMITH.

# ÍNDICE DE LAS MATERIAS

*Nota.* — En este Indice una T entre paréntesis (T) indica una tabla.

PÁGINAS

## MATEMÁTICAS.

Simbolos matemáticos ..... 31
Alfabeto Griego ..... 32

### Aritmética.

Factores y múltiplos (max fact, y div com, etc.) ..... 33
Fracciones (com denom ; sum, resta, multi, etc.) ..... 34
Decimales ..... 35
Fracciones decimales equivalentes a fracciones ordinarias (T). 36
Razón y Proporción ..... 36
Progresión ..... 38
Permutación, etc. (combinaciones, etc.) ..... 39
Percentaje, intereses, anualidades ..... 40
Interés simple ..... 41
Ecuación de pagos ..... 41
Interés compuesto ..... 42
» » (T) ..... 43
Anualidad, Fondo de reserva, amortización, etc ..... 44
Valor actual de una anualidad de 1000 (T) ..... 45
Anualidad para amortizar 1000 (T) ..... 46
Sistema duodecimal ..... 47
Numeros inversos (T) ..... 48-52
Numeros inversos (explicación) .. 52
Raices y potencias.
Cuadradas y cúbicas.
Tablas (T) ..... 55-67
Reglas ..... 63 y 67, etc.
Raices y potencias quintas (T). 69-70
Raiz cuad de la 5ª potencia .. 70-71
Logaritmos (Teoria) ..... 72

PÁGINAS

Carta y regla (logaritmicas) .. 76
Tablas logaritmicas y su manejo (T) ..... 80-93

### Geometría, Mensura y Trigonometría.

#### Lineas.

Definiciones ..... 94

#### Ángulos.

Definiciones ..... 95
Construcción ..... 96
Bisección ..... 96
Inscritos ..... 97
Complementos y suplementos .. 98
En un paralelogramo (reduc de mins a grads, etc.) ..... 98
Minutos y segundos, en decimales, de un grado y segundos en decimales de un minuto (T) ..... 99
Medida aproximada de los ángulos (ademas una (T)) ..... 100
Trigonometria plana ..... 101
Definiciones ..... 101
Valor numérico de las funciones de ciertos ángulos (T) .. 103
Propiedades, y relaciones de las lineas trigonométricas ..... 104
Formulas para la resolución de los triángulos ..... 105
Senos, tangentes, cotangentes y cosenos (T) ..... 106-150
Logaritmos de funciones trigonométricas. Introduccion ..... 151
Tabla Especial ..... 151*e*-151*i*
Tabla Principal ..... 151*j*-152*x*
Cuerdas. — Introduccion ..... 153
Cuerdas para radio 1 (T) .... 154-158

PÁGINAS

## Superficies.

Polígonos.
Regulares (T)..... 159
Triángulos.
Definiciones. Propiedades. Medidas, etc..... 159
Triángulos rectángulos..... 161
Problemas trigonométricos. Ejemplos..... 162
Correcciones por curvatura de la Tierra y refraccion de la luz. 167
Paralelogramosa..... 172
Trapecios..... 173
Polígonos..... 174
» regulares..... 174
Reducción de figuras..... 175-177
Circulos..... 177
Relaciones del círculo con otras figuras..... 178
Problemas relativos á los círculos..... 179
Diámetros en unidades y décimos (circunf. area) (T) (ejemplos)..... 180-185
Arcos de círculo.
Cuerda, longitud..... 186
Radio, flecha, ordenadas.... 187
Grandes radios (trazado)... 188
Arcos circulares de uso frecuente (T)..... 189
Desarrollo de los arcos circulares..... 190
Desarrollo de los arcos circulares (T)..... 191
Rectificacion de un arco circular. 192
Longitud de los arcos circulares para radio 1 (T)..... 193
Sectores circulares, anillos segmentos, etc..... 194
Segmento circular.
Áreas de segmentos circulares. 195
Areas de segmentos circulares (T)..... 196
Elipse..... 197-198
Ordenadas y periferia..... 198
Arco elíptico, desarrollo (T).. 199
Area de la elipse..... 200
Trazado, tangentes..... 200
Ovalo..... 200
Cimacio recto..... 202
La parábola..... 202
Propiedades de la —..... 202
Curva parabólica, longitud de la —..... 202
Area de —..... 203
Zona parabólica..... 203
Longitud de las curvas parabólicas (T)..... 203
Trazar una parábola (su tang, etc..... 203
La cycloide..... 204
Centro de gravedad de la —.... 205

PÁGINAS

## Sólidos.

Cuerpos regulares. tetrahedro, exahedro, etc..... 205
Teorema de Guldinus..... 205
Paralelepipedos, propiedades... 206
Prismas (diagonal, volumenes, etc..... 206
Cilindro truncado..... 207
Cilindro.
Volumen y superficie del —.. 208
Uñas cilindricas..... 209
Pirámides y conos..... 210
Troncos de pirámides y conos. 211
Prismoides..... 212
Cuñas..... 213
Esferas..... 214
Propiedades..... 214
Volúmen, superficie, etc. (T) 215-217
Segmento y zona de la — (volúmenes, etc.)..... 218
Cáscara esférica..... 218
Huso circular..... 219
Esferoide é elipsoide..... 219
Paraboloide..... 220
Tronco de paraboloide..... 220

## Peso Especifico.

Principios..... 221
Areometros de Beaumé, de Twaddell. de Nicolson, etc.... 222
Pesos especificos (T)..... 223-228

## Pesos y medidas.

Medidas de longitud y peso de los Estados Unidos y de Inglaterra..... 229
Monedas de todos los paises... 231
Oro y plata..... 232
Peso de Troy, de boticarios y Avoirdupois..... 232-233
Medidas de longitud (de los E. U. y Gran Bretaña)..... 233
Grados de longitud (T)..... 234
Medidas de superficie (Británicas y de los E. U.)..... 234
Medidas sólidas (Gran Bretaña y E. E. U. U.)..... 234
Medidas del Imperio Británico.. 235
Volúmenes y pesos del agua... 236
Unidades métricas..... 236-237
Sistema usual, — antiguo..... 238
Rusas..... 238
Españolas..... 238
Tablas de toda clase de conversión (long, sup, vol, pesos, tiempo, trabajo, calor, etc., y sus combinaciones.). 239
Introducción y explicación.... 239

PÁGINAS

Indice de las tablas..... 240
Equivalencias fundamentales. 240
Abreviaciones..... 241
Equivalentes y números de uso común ..... 241
Prefijos métricos..... 242
Tablas con toda clase de conversiones (vease indice de las tablas) ..... 242-263
(Longitudes, 242; Superficie, 243; Volúmenes, 244; Peso (fuerza), 245; Tiempo, 246; Trabajo y calor, 247; Long. por long. (pendientes), 247; Sup. por long, 247; Vol por long (superficies), 248; Peso por long, 249; Vol por sup (espesores), 249; Peso por sup (presiones), 250; Peso por vol (peso especifico), 250; Pesos de vols de agua, 251; Vol de pesos de agua, 251; Pesos de vols, 251; Vols de pesos de aire, 252; Long por tiempo (velocidad), 252; Superficie por tiempo, 652; vols por tiempo (descarga), 253; Peso por tiempo, 254; Trabajo por tiempo (potencia), 254; Trabajo por vol. 255; Trabajo por peso, 255; Valor por long, 255; Valor por sup, 256; Valor por volumen, 257; Valor por peso, 258; Valor por tiempo, 258; Valor de trabajo, 259; Long en tiempo, por tiempo (aceleración), 260; Volumen por superficie, dados los espesores, 260; Espesores, dados los vols por sup, 260; Vols por sup y por tiempo, 260; Velocidad, dados los vols por sup y por tiempo, 262; Vols por sup y por tiempo, dada la velocidad, 262).
Pendientes..... 264
Tablas de — (T)..... 264-265
Alturas y presiones de agua; tablas de — (T)..... 267-268
Tiempo. Definiciones, etc..... 268
Diversas especies de dias, meses, años, etc ..... 269
Arreglo de un reloj por las estrellas..... 269
Modelo de horas de los ferrocarriles ..... 270
Gnomónica ..... 272
Reloj de Sol (trazado vertical y hor) ..... 272
Medida de tablas de madera (T) ..... 273-278

PÁGINAS

**Levantamiento de planos.**

Pruebas de exactitud, distribución de error, etc..... 279
Cadenas, cintas, agujas ..... 291
Correcciones por seno y alargagamiento..... 291
Medida con la cadena..... 291
Correcciones por temperatura; terrenos inclinados..... 292
Trazado de la meridiana..... 294
Definiciones ..... 294
Por las estrellas circumpolares ..... 294
Por la Estrella Polar..... 295
Por medio de cualquier estrella en iguales altitudes..... 297
Por sombras solares simétricas. 297
Horas de elongación y culminación de la Estrella Polar.. 298
Angulos acimutales de la Polar (T)..... 299
Distancias polares y acimutales de la Estrella Polar (T). 300
Tránsito de Ingeniero ..... 301
Descripción y manejo del tránsito..... 302
Corrección de un tránsito común..... 304
Pelos cruzados, para reponerlos..... 307
Nivel de aire, para reponerlo. 307
Sextante de caja ó de bolsillo .. 308
Corrección de —..... 309
Sextante náutico..... 310
La Brújula..... 310
Corrección de —..... 310
Declinaciones y variaciones magnéticas ..... 312
Carta isogènica (de los Estados Unidos)..... 313
Declinación ..... 313
Variación..... 313
Desmagnetización..... 314
Curvas de nivel.
El nivel ..... 318
Corrección del nivel..... 320
Formas de las minutas de nivelación ..... 323
Nivel de mano, corrección .... 324
Nivel de albañil..... 325
Eclimetro ó nivel de pendiente..... 325
Nivelación por medio del barómetro y por la ebullición del agua..... 325
Efectos de la latitud..... 326
Tablas (T) ..... 327-328
Corrección por latitud ..... 328
Nivelación barométrica y termométrica (T).....329, 329*a*-329*b*
Corrección de temperatura (T) - 329*b*

# MATEMATICAS

## SÍMBOLOS MATEMÁTICOS

$+$ Más, positivo, adición.

$-$ Menos, negativo, sustracción.

$\pm$ Más ó menos, positivos ó negativos. Ej., $\sqrt{a^2} = \pm a$.

$\times$ Multiplicado por. Ej., $x \times y = x.y = xy$; $3 \times 4 = 12$.

$\div$ $:$ $/$ Dividido por. Ej., $a \div b = a : b = a / b = \frac{a}{b}$.

$::$ Proporción. Ej., $a : b :: c : d$, $a$ está con $b$ como $c$ está con d.

$=$ Igualdad, es igual; $a = b$; $a$ es igual $b$.

$>$ Mayor que. Ej., $6 > 5$.

$<$ Menor que. Ej., $5 < 6$.

$\neq$ No es igual.

$\lessgtr$ Mayor ó menor que.

$\ngtr$ No es mayor que.

$\nless$ No es menor que.

$\geqslant$ Es igual ó mayor que.

$\leqslant$ Es igual ó menor que.

$\propto$ Es proporcional, varía con.

$\infty$ Infinito.

$\perp$ Es perpendicular á.

$\angle$ Angulo.

$\backsim$ Es semejante á.

$\parallel$ Es paralelo á.

$\surd$ $\sqrt{\ }$ Raíz de. Ej., $\sqrt{a}$ ó $\sqrt{a}$ = raíz cuadrada de $a$; $\sqrt[3]{a}$ = raíz cúbica de $a$; $\sqrt[n]{a}$ = raíz $n$ de $a$.

$( )$ $[ ]$ $\{ \}$ Paréntesis. Las cantidades incluídas dentro de estos paréntesis, deben tomarse en conjunto.

$\because$ De aquí que. Por esta razón.

$\therefore$ Puesto que. Ya que.

$^\circ$ Grados.

$'$ Minutos de arco, pie.

$''$ Segundos de arco, pulgadas.

Los $'$ $''$ $'''$ minutos y segundos de tiempo se expresan : *min, seg.* etc. Prima, segunda, tercera, etc. Ej., $a'$, $a$ prima; $b''$, $b$ segunda; $b''$ $b$ tercera.

$\pi$ $\frac{\text{Circunferencia}}{\text{Diámetro}}$ = Relación de la circunferencia al diámetro 3.14159265.

E Módulo de elasticidad.

$e$ (epsilon). Base de los logaritmos neperianos ó hiperbólicos.

g Aceleración debida á la gravedad; aproximadamente igual á 32.2 pies por segundo = 9.81 metros por segundo.

## ALFABETO GRIEGO

Insertamos este alfabeto en obsequio de las personas que consultan libros científicos donde se emplean letras griegas.

| Letras griegas. | | Nombre. | Equivalente aproximado. | Generalmente usados para designar. |
|---|---|---|---|---|
| Mayúsculas. | Minúsculas. | | | |
| A | α | Alpha | a | Angulos, coeficientes. |
| B | β | Beta | b | — — |
| Γ | γ | Gamma | g | — gravedad. |
| Δ | δ | Delta | d | — densidad, variación. |
| E | ε | Epsilon | e (corta) | Base de los logaritmos hiperbólicos 2.7182818. Excentricidad en las secciones cónicas. |
| Z | ζ | Zeta | z | Coordenadas, coeficientes. |
| H | η | Eta | e (larga) | — — |
| Θ | θ ϑ | Theta | th | Angulos. |
| I | ι | Iota | i | |
| K | κ | Kappa | k | |
| Λ | λ | Lambda | l | Angulos, coeficientes, latitud. |
| M | μ | Mu | m | — — |
| N | ν | Nu | n | — |
| Ξ | ξ | Xi | x | Coordenadas. |
| O | ο | Omicron | o (corta) | |
| Π | π | Pi | p | Circunferencia ÷ diámetro.* |
| P | ρ | Rho | r | Radio, razón. |
| Σ | σ ς | Sigma | s | Distancia, espacio.† |
| T | τ | Tau | t | Temperatura, tiempo. |
| Υ | υ | Upsilon | u ó y | |
| Φ | φ | Phi | ph | Angulos, coeficientes. |
| X | χ | Chi | ch | |
| Ψ | ψ | Psi | ps | Angulos. |
| Ω | ω | Omega | o (larga) | Velocidades angulares. |

★ La letra minúscula π se emplea universalmente para designar el número de veces = 3.14159265...) que el diámetro de un círculo está contenido en su circunferencia, ó el radio en la semicircunferencia. En la medida circular de los ángulos, un ángulo se mide por el número de veces que el radio del círculo á que pertenece el ángulo, está contenido en el arco que subtende el ángulo. Como π representa el número de veces que el radio está contenido en la semicircunferencia, π es la medida en radios del arco de 180° ó una semicircunferencia.

Algunos matemáticos emplean la mayúscula Π (pi) para expresar el producto obtenido multiplicando entre sí los números 1, 2, 3, 4, etc.; por ej. $\Pi 4 = 1 \times 2 \times 3 \times 4 = 24$.

† La mayúscula Σ (sigma) se usa para expresar una suma. Por ejemplo, si en un sistema de fuerzas paralelas representamos cada fuerza por F, su resultante, como es igual á la suma algebráica de las fuerzas, se expresará así: $R = \Sigma F$.

# ARITMÉTICA

## FACTORES Y MÚLTIPLOS

(1) **Los factores** de cualquier número $n$ son los números cuyo producto $= n$. Ej. 17 y 4 son factores de 68; también 34 y 2; también 17, 2 y 2.

(2) **Números primos** son los que no tienen factores, excepto ellos mismos y la unidad; ej. 2, 3, 5, 19, 233.

(3) **El factor común, el común divisor**, ó **la medida común** de dos ó más números es un número divisor exacto de cada uno de ellos. Ej. 3 es divisor común de 6, 12 y 18.

(4) **El máximo factor común**, ó **máximo divisor común** de dos ó más números, se expresa así: **M. F. C.** ó **M. D. C.** Ej. 6 es **M. F. C.** de 6, 12 y 18.

(5) **Para encontrar el M. F. C.** de dos ó más números, búsquense los números ó factores primos de cada uno y multiplíquense juntos los que sean comunes á todos, tomando cada factor una sola vez. Ej. búsquese el M. F. C. de los números 78, 126, 234.

$$78 = 2\times3\times13$$
$$126 = 2\times3\times3\times7$$
$$234 = 2\times3\times3\times13$$

El M. F. C. $= 2\times3 = 6$.

(6) **Para encontrar el M. F. C.** de dos números muy grandes divídase el mayor por el menor, el menor por el primer residuo A; A por el segundo residuo B; B por el tercer residuo C y así sucesivamente hasta que no haya residuo. El último divisor es el M. F. C. Ej. búsquese el M. F. C. de 575 y 782.

575)782(1
575
A 207)575(2
414
B 161)207(1
161
C 46)161(3
138
D 23)46(2
46
0

M. F. C. = D = 23.

(7) **El múltiplo común** de dos ó más números, es un número exactamente divisible por cada uno de ellos.

(8) **El mínimo múltiplo común** de dos ó más números se expresa así: M. M. C.

(9) **Para encontrar el M. M. C.** de dos ó más números, se buscan los números primos de cada uno. Multiplíquense juntos los factores, tomando cada uno tantas veces cuantas esté repetido en el número que más lo contiene. Ej. para los números 7, 30 y 48.

$$7 = 7$$
$$30 = 2\times3\times5$$
$$48 = 2\times2\times2\times2\times3$$
$$\text{M. M. C.} = 7\times2\times2\times2\times2\times3\times5 = 1680.$$

(10) **Para encontrar el M.M. C.** de dos números grandes; búsquese el M. F. C., como se dijo arriba, y dividiendo á cada número por él, búsquese el otro factor y entonces hágase el producto de los factores, como antes. Ej. búsquese el M. M. C. de 575 y 782. Como arriba el

$$\text{M. F. C.} = 23;\ \frac{575}{23} = 25;\ \text{y}\ \frac{782}{23} = 34;\ \text{Luego}$$

$$575 = 23\times25$$
$$782 = 23\times34$$

y M. M. C. $= 23\times25\times34 = 19{,}550$.

## FRACCIONES

(1) **El común denominador** de dos ó más fracciones es el múltiple común de sus denominadores.

(2) **El mínimo común denominador** ó M. C. D. de dos ó más fracciones es el M. M. C. de sus denominadores.

(3) **Para reducir á un común denominador,** sea

N = el nuevo numerador de cualquier fracción.
n = el antiguo numerador.
d = el antiguo denominador.
C = el común denominador.

Entonces $$N = n\frac{C}{d}.$$

Así, $\frac{3}{4}, \frac{5}{6}, \frac{7}{8}$. C = M. M. C. de los denominadores = 24.

$$\frac{3}{4} = \frac{3 \times \frac{24}{4}}{4 \times \frac{24}{4}} = \frac{3 \times 6}{4 \times 6} = \frac{18}{24}; \quad \frac{5}{6} = \frac{5 \times 4}{6 \times 4} = \frac{20}{24}; \quad \frac{7}{8} = \frac{7 \times 3}{8 \times 3} = \frac{21}{24}.$$

Si los denominadores no tienen factor común, entonces C = al producto de todos los denominadores; $\frac{C}{d}$ = al producto, P, de los *otros* denominadores y N = Pn.

Ej., $\frac{2}{3}, \frac{1}{4}, \frac{5}{7}$. C = 84.

$$\frac{2}{3} = \frac{2 \times 4 \times 7}{84} = \frac{56}{84}; \quad \frac{1}{4} = \frac{1 \times 3 \times 7}{84} = \frac{21}{84}; \quad \frac{5}{7} = \frac{5 \times 3 \times 4}{84} = \frac{60}{84}.$$

(4) **Suma y resta.** Si es necesario redúzcanse las fracciones á un común denominador, el menor será mejor. Súmense ó réstense los numeradores. Ej.

$$\frac{1}{2} + \frac{1}{2} = \frac{2}{2} = 1; \quad \frac{3}{4} + \frac{1}{4} = \frac{4}{4} = 1; \quad \frac{3}{4} + \frac{5}{9} = \frac{27}{36} + \frac{20}{36} = \frac{47}{36} = 1\frac{11}{36};$$

$$\frac{3}{4} + \frac{7}{8} = \frac{6}{8} + \frac{7}{8} = \frac{13}{8} = 1\frac{5}{8}.$$

$$\frac{3}{4} - \frac{1}{4} = \frac{2}{4} = \frac{1}{2}; \quad \frac{3}{4} - \frac{5}{9} = \frac{27}{36} - \frac{20}{36} = \frac{7}{36}; \quad \frac{7}{8} - \frac{3}{4} = \frac{7}{8} - \frac{6}{8} = \frac{1}{8}.$$

(5) **Multiplicación.** Multipliquense todos les numeradores y todos los denominadores. El producto es una fracción que tiene por numerador el producto de los numeradores y por denominador el producto de los denominadores. Si se quiere simplificar, divídanse el numerador y denominador del quebrado producto por su M. D. C. Ej.

$$\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}; \quad \frac{3}{4} \times \frac{1}{4} = \frac{3}{16}; \quad \frac{3}{4} \times \frac{5}{9} \times \frac{2}{3} = \frac{5}{18};$$

$$\frac{4}{7} \times 1\frac{2}{3} = \frac{25}{7} \times \frac{5}{3} = \frac{125}{21} = 5\frac{20}{21}; \quad \frac{2}{3} \times \frac{3}{5} = \frac{2}{5};$$

$$\frac{3}{4} \text{ de } \frac{1}{2} \text{ de } \frac{5}{3} \text{ de } \frac{7}{5} = \frac{3}{4} \times \frac{1}{2} \times \frac{5}{3} \times \frac{7}{5} = \frac{7}{8}.$$

(6) **División.** Multipliquense por el quebrado divisor invertido.

$$\frac{1}{2} \div \frac{1}{2} = \frac{1}{2} \times \frac{2}{1} = \frac{2}{2} = 1; \quad \frac{3}{4} \div \frac{1}{4} = \frac{3}{4} \times \frac{4}{1} = \frac{3}{1} = 3$$

$$\frac{3}{4} \div \frac{5}{9} = \frac{3}{4} \times \frac{9}{5} = \frac{27}{20} = 1\frac{7}{20};$$

$$3\frac{4}{7} \div 1\frac{2}{3} = \frac{25}{7} \div \frac{5}{3} = \frac{25}{7} \times \frac{3}{5} = \frac{5}{7} \times \frac{3}{1} = \frac{15}{7} = 2\frac{1}{7};$$

$$5 \div \frac{7}{8}\frac{8}{7} = 5 \times = \frac{40}{7} = 5\frac{5}{7}.$$

(7) Se dice que una fracción está **simplificada** cuando su numerador y denominador no tienen factor común. Ej.

$$\frac{34}{85} \text{ simplificada} = \frac{2}{5}.$$

(8) Para simplificar una fracción ó reducirla á **su más sencilla expresión.** Divídase el numerador y denominador por su M. F. C. Ej. simplifíquese á $\frac{34}{85}$.

$$\text{M. F .C. de } 34 \text{ y } 85 = 17; \quad \frac{34}{85} = \frac{34 \div 17}{85 \div 17} = \frac{2}{5}.$$

## DECIMALES

(9) **Multiplicación.** Las cifras decimales del producto son iguales á la suma de las que contienen los factores. Ej.

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Factores: | 100 | × 3 | × 3.5 | × 0.004 | × 465.21 | = | 1953.882000 | | |
| Número de decimales: | 0 | + 0 | + 1 | + 3 | + 2 | = | | 6 | |

(10) **División.** El número de cifras decimales del cociente = á las que contier el dividendo menos las que contiene el divisor. Ej.

$$\frac{5.125}{4.1} = 1.25; \quad \frac{5}{4} = \frac{5.00}{4} = 1.25; \quad \frac{3}{4} = \frac{3.00}{4} = 0.75; \quad \frac{0.42}{0.0021} = \frac{0.4200}{0.0021} = 200$$

Cuando el divisor es una fracción ó un número mixto, debemos multiplicar á ambos, divisor y dividendo, por la menor potencia de 10 que convierta al divisor en número entero. Ej.

$$\frac{2.679454}{0.0062} = \frac{26,794.54}{62} = 432.17.$$

(11) **Para reducir una fracción ordinaria á fracción decimal,** divídase el numerador por el denominador. Ej. $\frac{32}{40} = 0.8$; $1\frac{3}{5} = \frac{8}{5} = 1.6$.

**Tabla 1. Fracciones decimales equivalentes á las fracciones ordinarias.**

| Octavos. | Dieciseisavos. | Treintaidosavos. | Sesentaicuatroavos. | | Octavos. | Dieciseisavos. | Treintaidosavos. | Sesentaicuatroavos. | |
|---|---|---|---|---|---|---|---|---|---|
| | | | 1 | .015625 | | | | 33 | .515625 |
| | | 1 | 2 | .03125 | | | 17 | 34 | .53125 |
| | | | 3 | .046875 | | | | 35 | .546875 |
| | 1 | 2 | 4 | .0625 | | 9 | 18 | 36 | .5625 |
| | | | 5 | .078125 | | | | 37 | .578125 |
| | | 3 | 6 | .09375 | | | 19 | 38 | .59375 |
| | | | 7 | .109375 | | | | 39 | .609375 |
| 1 | 2 | 4 | 8 | .125 | 5 | 10 | 20 | 40 | .625 |
| | | | 9 | .140625 | | | | 41 | .640625 |
| | | 5 | 10 | .15625 | | | 21 | 42 | .65625 |
| | | | 11 | .171875 | | | | 43 | .671875 |
| | 3 | 6 | 12 | .1875 | | 11 | 22 | 44 | .6875 |
| | | | 13 | .203125 | | | | 45 | .703125 |
| | | 7 | 14 | .21875 | | | 23 | 46 | .71875 |
| | | | 15 | .234375 | | | | 47 | .734375 |
| 2 | 4 | 8 | 16 | .25 | 6 | 12 | 24 | 48 | .75 |
| | | | 17 | .265625 | | | | 49 | .765625 |
| | | 9 | 18 | .28125 | | | 25 | 50 | .78125 |
| | | | 19 | .296875 | | | | 51 | .796875 |
| | 5 | 10 | 20 | .3125 | | 13 | 26 | 52 | .8125 |
| | | | 21 | .328125 | | | | 53 | .828125 |
| | | 11 | 22 | .34375 | | | 27 | 54 | .84375 |
| | | | 23 | .359375 | | | | 55 | .859375 |
| 3 | 6 | 12 | 24 | .375 | 7 | 14 | 28 | 56 | .875 |
| | | | 25 | .390625 | | | | 57 | .890625 |
| | | 13 | 26 | .40625 | | | 29 | 58 | .90625 |
| | | | 27 | .421875 | | | | 59 | .921875 |
| | 7 | 14 | 28 | .4375 | | 15 | 30 | 60 | .9375 |
| | | | 29 | .453125 | | | | 61 | .953125 |
| | | 15 | 30 | .46875 | | | 31 | 62 | .96875 |
| | | | 31 | .484375 | | | | 63 | .984375 |
| 4 | 8 | 16 | 32 | .5 | 8 | 16 | 32 | 64 | 1. |

**(12) Para reducir una fracción decimal á fracción ordinaria.** Póngasele por denominador 1 y redúzcase á su más sencilla expresión la fracción que resulte. Ejemplo,

$$0.25 = \frac{0.25}{1.00} = \frac{25}{100} = \frac{1}{4};\quad 0.75 = \frac{75}{100} = \frac{3}{4};\quad 0.890625 = \frac{890625}{1000000} = \frac{57}{64}.$$

**(13) Se llaman fracciones periódicas,** aquellas en que hay una ó más decimales que se repiten indefinidamente. Ej. $\frac{1}{3} = 0.3333\ldots\ldots$, $\frac{10}{7} = 1.428571428571\ldots\ldots$ La parte periódica se señala así : $0.\overline{3}$, $1.\overline{428571}$; ó así : 0.*3, 1.*428571.....

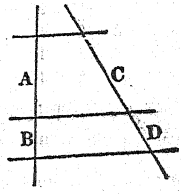
## RAZÓN Y PROPORCIÓN

**(1) Razón.** La razón entre dos cantidades como A y B, se expresa por su cociente, $\frac{A}{B}$ ó $\frac{B}{A}$. La razón entre 10 y 5 es $= \frac{10}{5} = 2$; entre 5 y 10 $= \frac{5}{10} = 0.5$.

(2) **La doble razón** es la razón entre los cuadrados de los números. Ej. $\frac{A^2}{B^2}$ es la doble razón entre A y B.

(3) **Proporción** es la igualdad de razones. Ej. $\frac{10}{5} = \frac{12}{6} = \frac{1266}{633} = 2$. En la figura que representa segmentos A, B, C, D, entre líneas paralelas; A : B :: C : D, ó $\frac{A}{B} = \frac{C}{D}$.

(4) El primero y cuarto términos A y D se llaman **extremos**; y el segundo y tercero B y C se llaman **medios**. El primer término A ó C de cada razón, se llama **antecedente** y el segundo B ó D **consecuente**. El término D se llama la **cuarta proporcional** de A, B, y C.



(5) En una proporción, A : B = C : D, se tiene :

Producto de los extremos = producto de los medios. AD = BC.

Alternando. $\frac{A}{B} = \frac{C}{D}$; $\frac{A}{C} = \frac{B}{D}$.

Invirtiendo. $\frac{B}{A} = \frac{D}{C}$; $\frac{B}{D} = \frac{A}{C}$; $\frac{D}{B} = \frac{C}{A}$.

Componiendo sumando. $\frac{A+B}{A} = \frac{C+D}{C}$; $\frac{A+B}{B} = \frac{C+D}{D}$.

Componiendo restando. $\frac{A-B}{A} = \frac{C-D}{C}$; $\frac{A-B}{B} = \frac{C-D}{D}$.

Componiendo dividiendo. $\frac{A+B}{A-B} = \frac{C+D}{C-D}$.

También se tiene :

$$\frac{mA}{mB} = \frac{A}{B} = \frac{C}{D} = \frac{nA}{nB} = \frac{nC}{nD}; \quad \frac{mA}{nB} = \frac{mC}{nD}; \quad \frac{A^n}{B^n} = \frac{C^n}{D^n}; \quad \frac{\sqrt[n]{A}}{\sqrt[n]{B}} = \frac{\sqrt[n]{C}}{\sqrt[n]{D}}.$$

(6) Si en la proporción A : B = C : D, se tiene que B = C = $m$, entonces, $\frac{A}{m} = \frac{m}{D}$; ó $m^2 = AD$, ó $m = \sqrt{AD}$.

(7) En este caso se dice que $m$ es **media proporcional** entre A y D; y D se llama la **tercera proporcional** entre A y $m$.

Una **proporción continua** es una serie de razones iguales como :

$$A : B = C : D = E . F, \text{ etc.} = R; \quad \frac{A}{B} = \frac{C}{D} = \frac{E}{F}, \text{ etc.} = R.$$

En la proporción continua,

$$\frac{A + C + E + \text{etc.}}{B + D + F + \text{etc.}} = \frac{A}{B} = \frac{C}{D} = \frac{E}{F}, \text{ etc.} = R.$$

Si $\frac{A}{B} = \frac{C}{D}$; $\frac{A'}{B'} = \frac{C'}{D'}$; $\frac{A''}{B''} = \frac{C''}{D''}$; entonces $\frac{A\,A'\,A''}{B\,B'\,B''} = \frac{C\,C'\,C''}{D\,D'\,D''}$, etc.

**8)** Sean A, B y C tres números cualesquiera, entonces

$$\frac{A}{C} = \frac{A}{B} \cdot \frac{B}{C}, \text{ y } \frac{A}{B} = \frac{A}{C} \cdot \frac{C}{B}.$$

**(9) Proporción recíproca ó inversa.** — Dos cantidades, se dice que están en razón inversa, cuando la razón $\frac{A}{B}$ de dos valores A y B de la una es igual á la recíproca $\frac{B}{A'}$ de la razón de otros dos valores A', B' correspondientes, de la otra. Ej.: Sea A = a una velocidad de dos millas por hora, y B = 3 millas por hora. Entonces el tiempo requerido por milla en horas, será respectivamente $A' = \frac{1}{A} = \frac{1}{2}$, $B' = \frac{1}{B} = \frac{1}{3}$. En este caso A : B = B' : A', ó bien

$$\frac{A}{B} = \frac{B'}{A'}, \text{ ó } \frac{2}{3} = \frac{\frac{1}{3}}{\frac{1}{2}} = \frac{2}{3} = 1 \div \frac{A'}{B}.$$

**(10)** Si dos números variables A y B son recíprocamente proporcionales, de modo que A' : B' = B'' : A'' el producto A' A'' de cualquiera de los dos valores de uno de los números, es igual al producto B' B'' de los dos valores correspondientes del otro.

**(11)** La aplicación de la proporción á los problemas prácticos, se llama á veces **Regla de tres.** Ejemplo de una **regla de tres simple** : si tres hombres cargan 10,000 ladrillos en cierto tiempo, ¿cuántos pueden cargar 6 hombres en el mismo tiempo? Como están 3 con 6 hombres, así están 10,000 con 20,000 ladrillos; ó bien $10{,}000 \times \frac{6}{3} = 20{,}000$ ladrillos.

Si 3 hombres invierten 10 horas para cargar cierto número de ladrillos, ¿cuántas horas invertirán 6 hombres para cargar el mismo número? Como están 6 con 3 hombres, así están 10 horas con 5 horas, ó bien 10 horas $\times \frac{3}{6} = 5$ horas.

**(12) Regla de tres compuesta.** — Si 3 hombres cargan 4,000 ladrillos en 2 días, ¿cuántos hombres pueden cargar 12,000 en 3 días? En este caso 4,000 ladrillos requieren 3 hombres en 2 días ó 6 hombres en un día, 12,000 necesitarán tres veces más, ó sean $6 \times \frac{12{,}000}{4{,}000} = 6 \times 3 = 18$ hombres en un día ó 18 *hombres-días;* y como el trabajo se va á hacer en 3 días, serán $\frac{18}{3} = 6$ hombres que se necesitan.

## PROGRESIÓN

**(1)** Se dice que una serie de números están en *progresión aritmética* cuando cada número difiere del que le precede, en una misma cantidad. Ej. : — 2, — 1, 0, 1, 2, 3, etc., aquí la diferencia es 1; ó bien 4, 3, 2, 1, 0, — 1, — 2, etc., en que la diferencia es = — 1; ó bien — 4, — 2, 0, 2, 4, 6, etc., en que la diferencia es 2; ó bien 1½, 1¼, 1, ¾, ½, ¼, 0, — ¼, — ½, etc., en que la diferencia = — ¼.

**(2)** En cualesquiera de estas series los números se llaman términos. Sean, $a$ el primer término; $l$ el último; $d$ la diferencia constante; $n$ el número de términos, y $s$ la suma de estos términos. Entonces

| Se desea conocer. | Conociendo. | |
|---|---|---|
| | $a\ d\ n$ | $l = a + (n-1)\,d$ |
| | $a\ d\ s$ | $l = -\frac{1}{2}d \pm \sqrt{2ds + \left(a - \frac{1}{2}d\right)^2}$ |
| | $a\ d\ n$ | $s = \frac{1}{2}n\,[2a + (n-1)\,d]$ |

| | | |
|---|---|---|
| $a$ | $d\ l\ s$ | $a = \frac{1}{2}d \pm \sqrt{\left(l + \frac{1}{2}d\right)^2 - 2ds}$ |
| $n$ | $a\ d\ s$ | $n = \frac{d - 2a \pm \sqrt{(2a - d)^2 + 8ds}}{2d}$ |
| $n$ | $d\ l\ s$ | $n = \frac{2l + d \pm \sqrt{(2l + d)^2 - 8ds}}{2d}$ |

§ (3) **Progresión geométrica.** Se dice que una serie de números están en progresión geométrica, cuando uno cualquiera de ellos dividido por el anterior da el mismo cociente. Ej. : $\frac{1}{9}$, $\frac{1}{3}$, 1, 3, 9, 27, etc., aquí el cociente es 3; ó bien 48, 24, 12, 6, 3, $1\frac{1}{2}$, $\frac{3}{4}$, $\frac{3}{8}$, etc., aquí el cociente es $= \frac{1}{2}$.

(4) Sea $a$ el primer término; $l$ el último; $r$ la razón ó cociente constante; $n$ el número de términos y $s$ la suma de los términos. Entonces

| Se desea conocer. | Conociendo. | |
|---|---|---|
| $l$ | $a\ r\ n$ | $l = ar^{n-1}$ * |
| $l$ | $a\ r\ s$ | $l = \frac{a + (r-1)s}{r}$ |
| $l$ | $r\ n\ s$ | $l = \frac{(r-1)sr^{n-1}}{r^n - 1}$ |
| $s$ | $a\ n\ l$ | $s = \frac{\sqrt[n-1]{l^n} - \sqrt[n-1]{a^n}}{\sqrt[n-1]{l} - \sqrt[n-1]{a}}$ |
| $s$ | $r\ n\ l$ | $s = \frac{lr^n - l}{r^n - r^{n-1}}$ |
| $r$ | $a\ n\ l$ | $r = \sqrt[n-1]{l \div a}$ |

## PERMUTACIÓN, Etc.

(1) **Permutación.** Las permutaciones sirven para encontrar en cuántas posiciones puede ser dispuesto en hilera un número cualquiera de cosas. Para hacer esto, multipliquense juntos todos los números sucesivos desde 1 hasta el número de objetos, así : ¿En cuántas posiciones en una misma línea pueden colocarse 9 objetos?

$$1 \times 2 \times 3 \times 4 \times 5 \times 6 \times 7 \times 8 \times 9 = 362{,}880 \text{ posiciones.}$$

(2) **Combinaciones.** ¿Cuántas combinaciones diferentes pueden formarse con un número de objetos, entrando en cada combinación cierto número? Para saber esto, fíjese primero la cifra que indica el número de objetos y después la serie de números que siguen cuya diferencia sea 1 hasta que haya *por todo* tantos números cuantos objetos van á entrar en cada combinación. Luego, á partir del número de objetos que van á entrar en cada combinación, fórmese otra serie descendente, con la misma diferencia de 1. Multipliquense juntos todos los números de la primera operación, para formar un producto y todos los de la segunda para formar otro y divídase el primer producto por el segundo.

Ejemplo : ¿Cuántas combinaciones diferentes de 4 números cada una pueden hacerse con los nueve números 1, 2, 3, 4, 5, 6, 7, 8 y 9 ó 9 objetos cualesquiera?

$$\frac{9 \times 8 \times 7 \times 6}{1 \times 2 \times 3 \times 4} = \frac{3024}{24} = 126 \text{ combinaciones.}$$

* Las ecuaciones que contienen potencias ó radicales son á veces resueltas con más facilidad por los logaritmos.

**(3) Aligación.** Sirve para encontrar el valor de una mezcla de diferentes ingredientes cuando la cantidad y valor de cada uno de estos últimos son conocidos.

Ejemplo : ¿Cuál es el valor de una libra de la mezcla de 20 libras de á 15 centavos la libra con 30 libras de á 25 centavos la libra?

| lbs. | cts. | cts. |
|---|---|---|
| $20 \times 15 =$ | | 300 |
| $30 \times 25 =$ | | 750 |
| 50 lbs. | | 1,050 cts. |

por tanto $\frac{1,050}{50} = 21$ cts. Resultado.

## TANTO POR CIENTO (Porcentaje), INTERÉS, ANUALIDADES

**(1)** La razón se expresa á menudo con la palabra *por*. Así, hablando de una pendiente, se dice: 105.6 pies (=30 m. 48) por milla ó por 5,280 pies (=1,680 m. 38). Cuando los dos términos de la razón se refieren á cantidades de la misma especie y denominacion, la razón se expresa á menudo en un *porcentage* ó *tanto por ciento*. Así, una pendiente de 105.6 pies por milla ó por 5,280 pies, equivale á una pendiente de 0.02 de pie por pie* ó de metro por metro, ó de legua por legua, etc.; es decir, de 2 *por* 100.

**(2)** Un *cincuentavo* ó 1 por 50, equivale á 2 por 100, ó dos centésimos. Del mismo modo $\frac{1}{4} = 25$ por ciento, $\frac{3}{4} = 3 \times 25$ por ciento $= 75$ por ciento, etc. Por tanto, para encontrar el tanto por ciento equivalente á una razón, dividase 100 veces el primer término por el segundo. Ej. : En un concreto (argamasa de cemento) de 1 parte de cemento, 2 de arena y 5 de piedra picada, por todo 8 partes (por peso)†.

| | | | |
|---|---|---|---|
| Cemento | $= \frac{1}{8} = 0.125 =$ | 12.5 | por ciento del total. |
| Arena | $= \frac{2}{8} = 0.250 =$ | 25.0 | » » |
| Piedra | $= \frac{5}{8} = 0.625 =$ | 62.5 | » » |
| Concreto | $= \frac{8}{8} = 1.000 =$ | 100.0 | por ciento del total. |

**(3)** El tanto por ciento tiene una amplia aplicación en asuntos de dinero: y el pago de servicios en las operaciones se basa á menudo en el monto de las sumas que se negocian. Por ejemplo : A un agente comprador ó vendedor de valores hay que pagarle una comisión que forma un tanto por ciento del valor de la cosa negociada; el premio pagado por aseguro, es un tanto por ciento del valor de los bienes asegurados.

### Interés.

**(4)** Interés es la renta que se paga por el dinero prestado. La suma prestada es el **capital** y el número de centavos pagados mensual ó anualmente por cada peso ó unidad de moneda, ó el número de pesos por cada cien pesos, es el **interés.** Éste siempre se fija en un tanto por ciento y se expresa con este signo %;

---

* Las fracciones como $\frac{1}{8}, \frac{5}{16}$, etc., ó las decimales equivalentes .125, .3125, etc., están comparadas con la *unidad* ó 1 ; pero al tratarse de un *porcentaje* el primer término de la razón ó cociente se compara con *100 unidades* del segundo término ó dividendo. Se cometen muchos errores por olvidar esta distinción. Ej. : .06 (seis por ciento) se lee equivocadamente á veces : seis centésimos de uno por ciento ó *seis centesimos* por ciento.

† Para las proporciones por volúmenes véanse en el capítulo *Argamasa-Cemento* los números 40 y siguientes y los números 5 y siguientes del capítulo *Pruebas* de la misma sección.

así una suma al 3% anual, expresa que cada cien unidades devengan de interés 3 unidades por año.

(5) Si el interés se paga al prestamista á proporción que se produce, se dice que el dinero está á **interés simple;** pero, si el interés se va periódicamente agregando al capital, para que, aumentándolo, devengue á su vez interés, se dice que el dinero está á **interés compuesto.**

## Interés simple.

(6) Al fin del año el interés del capital P á la rata ó interés de $r$ por unidad será $Pr$ y la suma A de capital é intereses será

$$A=P+Pr=P\ (1+r)$$

(7) Al término de un número de años $n$, el interés será $Prn$ (véase el lado derecho de la figura 1) y,

$$A=P+Prn=P\ (1+rn)$$

Ejemplo : Sea P=$865.32; $r$=3 por ciento ó 0.03 y $n$=1 año, 3 meses y 10 días=1 año y 100 días=$1\frac{100}{365}$ años=1.274 años. Entonces $A=P\ (1+rn)=$ $=865.32\times(1+0.03\times1.274)=865.32\times1.03822=\$898.39$.

(8) Para conocer el valor actual P de una suma capitalizada, que se entregará dentro de $n$ años, se tendrá despejando á P en la ecuación dicha

$$P=\frac{A}{1+rn}$$

Ejemplo : ¿Cuál es el valor actual P de una suma que en un año, 3 meses y 10 días al 3% anual se convierte en $898.39. Se tiene $P=\frac{898.39}{1+0.03\times1.274}=865.32$.

(9) En el comercio se calculan los intereses aproximadamente, suponiendo el año de 12 meses de á 30 días. Así el 6% de interés anual en 2 meses=60 días=1 por ciento; 1 mes=30 días=½%; 6 días=0.1 por ciento. Ej. : ¿Cuál es el interés de $1,264.35 en 5 meses, 28 días al 5% anual?

| | |
|---|---|
| Capital | $1,264.35 |
| Intereses, 2 meses, 1% | 12.64 |
| — 2 — 1% | 12.64 |
| — 1 — ½% | 6.32 |
| — 20 días, ⅓% | 4.21 |
| — 6 — 0.1% | 1.26 |
| — 2 — 1/30% | 0.42 |
| Intereses al 6% | $37.49 |
| Se deduce un sexto | 6.25 |
| Interés al 5% | $31.24 |

## Ecuación de pagos.

(10) A le debe á B $1,200; de los cuales 400 deben pagarse en 3 meses; 500 en 4 meses y 300 en 6 meses. Todas devengan interés hasta ser pagados, pero se ha convenido en que la suma se pague junta. Se pregunta : ¿En qué tiempo debe pagársela para que ninguno se perjudique?

| | meses. |
|---|---|
| 400 × 3 | = 1,200 |
| 500 × 4 | = 2,000 |
| 300 × 6 | = 1,800 |
| 1,200 | 5,000 |

Tiempo medio $\frac{5,000}{1,200}$ = 4 1/6 meses. Respuesta.

## Interés compuesto.

**(11)** Se acostumbra acumular los intereses por año, por semestre ó por trimestre Si por años (véase el lado izquierdo de la fig. 1).

al final de 1 año $A=P\,(1+r)$

— 2 años $A=P\,(1+r)\,(1+r)=P\,(1+r)^2$

— $n$ — $A=P\,(1+r)^n$ y

$$P=\frac{A}{(1+r)^n}=A\,(1+r)^{-n}$$

$$\frac{A}{P}=(1+r)^n$$

**(12)** Si los intereses se acumulan $q$ veces por año, se tendrá

$$\frac{A}{P}=\left(1+\frac{r}{q}\right)^{qn}.$$

**(13)** E capital P, se llama á veces **valor actual** de la suma A. Así, en la tabla que sigue $1.00 es el **valor actual** de $2.191 dentro de 20 años al 4% anual al interés compuesto.

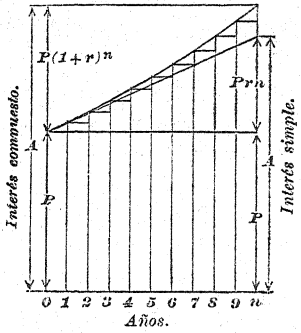


**Fig. 2.**

## Tabla 2. Interés compuesto.

Valor de una unidad monetaria cualquiera á interés compuesto.

| Años. | 3 % | 3½ % | 4 % | 4½ % | 5 % | 5½ % | 6 % | 6½ % |
|---|---|---|---|---|---|---|---|---|
| 1 | 1.030 | 1.035 | 1.040 | 1.045 | 1.050 | 1.055 | 1.060 | 1.065 |
| 2 | 1.061 | 1.071 | 1.082 | 1.092 | 1.103 | 1.113 | 1.124 | 1.134 |
| 3 | 1.093 | 1.109 | 1.125 | 1.141 | 1.158 | 1.174 | 1.191 | 1.208 |
| 4 | 1.126 | 1.148 | 1.170 | 1.193 | 1.216 | 1.239 | 1.262 | 1.286 |
| 5 | 1.159 | 1.188 | 1.217 | 1.246 | 1.276 | 1.307 | 1.338 | 1.370 |
| 6 | 1.194 | 1.229 | 1.265 | 1.302 | 1.340 | 1.379 | 1.419 | 1.459 |
| 7 | 1.230 | 1.272 | 1.316 | 1.361 | 1.407 | 1.455 | 1.504 | 1.554 |
| 8 | 1.267 | 1.317 | 1.369 | 1.422 | 1.477 | 1.535 | 1.594 | 1.655 |
| 9 | 1.305 | 1.363 | 1.423 | 1.486 | 1.551 | 1.619 | 1.689 | 1.763 |
| 10 | 1.344 | 1.411 | 1.480 | 1.553 | 1.629 | 1.708 | 1.791 | 1.877 |
| 11 | 1.384 | 1.460 | 1.539 | 1.623 | 1.710 | 1.802 | 1.898 | 1.999 |
| 12 | 1.426 | 1.511 | 1.601 | 1.696 | 1.796 | 1.901 | 2.012 | 2.129 |
| 13 | 1.469 | 1.564 | 1.665 | 1.772 | 1.886 | 2.006 | 2.133 | 2.267 |
| 14 | 1.513 | 1.619 | 1.732 | 1.852 | 1.980 | 2.116 | 2.261 | 2.415 |
| 15 | 1.558 | 1.675 | 1.801 | 1.935 | 2.079 | 2.232 | 2.397 | 2.572 |

El interés compuesto de M unidades cualesquiera á cualquier rata $r$ en años = M × el interés compuesto de la unidad á la misma rata $r$ y por en años

### Anualidad, fondo de reserva, amortización, depreciación.

(**14**) Hay casos en que cierta suma o capital pagado una sola vez, se le destina á cumular sus propios intereses, simples o compuestos; en otros se hacen pagos períodicos, comunmente anuales, llama dos **anualidades**, para acumular también sus intereses, generalmente compuestos.

(**15**) Por ejemplo, se pone aparte ó se deposita una suma anual que con sus intereses compuestos forma un **fondo de reserva** destinado á cubrir una deuda.

Este sistema se emplea á veces para pagar á plazos las construcciones ú obras de ingeniería. Este proceso se llama de **amortización**.

**(16)** Al valorar la obra se hace un cálculo para su **depreciación**, con el tiempo, uso, etc. Hecha esta apreciación se calcula la vida ó duración de la obra, en años $n$ y se busca la anualidad $p$, que á la rata $r$ de interés compuesto, sea suficiente para reponer la obra al cabo del tiempo $n$, cuando el uso, etc., la hayan destruído.

**(17)** El **valor actual** ó **capitalización** $W$, fig. 2, de una anualidad $p$ para un número dado de años $n$, es una suma que, si se la coloca ahora, á interés compuesto, á la rata $r$, llega, al cabo de dicho tiempo, á valer la misma suma A, que se alcanzó con dicha anualidad.

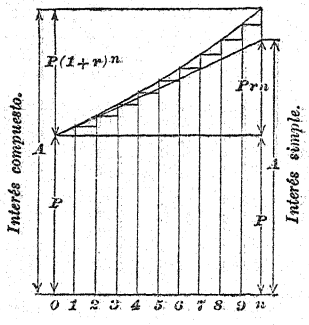

Fig. 1.

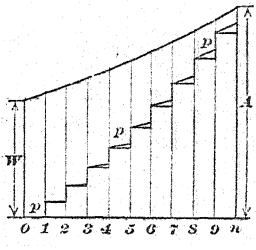

Fig. 2.

**(18) Ecuaciones para interés compuesto y anualidades** (véanse figs. 1 y 2).

| | | |
|---|---|---|
| P = capital; | $r$ = interés; | $n$ = número de años; |
| A = suma total; | $p$ = anualidad; | $W$ = valor actual. |

Se supone el interés compuesto y las anualidades depositadas al final de cada año.

### Interés compuesto.

(1) El monto A de una unidad monetaria cualquiera al cabo de $n$ años (véase **11**) es $A=(1+r)^n$.

(2) Por tanto, como el valor actual de la suma $(1+r)^n$ pagadera á los $n$ años es 1 (dólar, franco, etc.) (véase **(1)**); siguiendo el mismo razonamiento la unidad $1, por ejemplo, pagadero á los $n$ años, vale hoy $W = \dfrac{1}{(1+r)^n} = (1+r)^{-n}$.

### Anualidades.

3) Considerada $r$ como una anualidad que se acumula, al cabo de $n$ años, valdrá $(1+r)^n-1$, pues hay que rebajar el capital primitivo 1, para que quede sólo la acumulación de la anualidad $r$. Si la anualidad $r$ vale á los $n$ años $(1+r)^n-1$ **el monto A de la anualidad** de $1, valdrá á los $n$ años

$$A = \frac{(1+r)^n - 1}{r}.$$

(4) Para **el valor actual** $W$ **de una anualidad** de $1 durante $n$ años, se tiene, de las ecuaciones (1) y (3) :

$$(1+r)^n : 1 = \frac{(1+r)^n - 1}{r} : W. \quad \text{Así } W = \frac{(1+r)^n - 1}{(1+r)^n r} = \frac{1 - \frac{1}{(r+1)^n}}{r}.$$

(Véase tabla 3.)

(5) La anualidad durante $n$ años que corresponde á lo que puede ganar $1, es

$$p = \frac{1}{W} = \frac{r}{1 - \frac{1}{(1+r)^n}}.$$

(6) La anualidad que en $n$ años llega á valor $1, es :

$$p' = p - r = \frac{1}{W} - r = \frac{r}{1 - \frac{1}{(1+r)^n}} - r = \frac{r}{(1+r)^n - 1}.$$

**Tabla 3. — Valor actual de una anualidad de 1000** (dólares francos, etc.). Véase ecuación 4.

| | A interés compuesto. | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Años. | 2½ % | 3 % | 3½ % | 4 % | 4½ % | 5 % | 5½ % | 6 % |
| 5 | 4,646 | 4,580 | 4,515 | 4,452 | 4,390 | 4,329 | 4,268 | 4,212 |
| 10 | 8,752 | 8,530 | 8,316 | 8,111 | 7,913 | 7,722 | 7,538 | 7,360 |
| 15 | 12,381 | 11,938 | 11,517 | 11,118 | 10,740 | 10,380 | 10,037 | 9,712 |
| 20 | 15,589 | 14,877 | 14,212 | 13,590 | 13,008 | 12,462 | 11,950 | 11,470 |
| 25 | 18,424 | 17,413 | 16,482 | 15,622 | 14,828 | 14,094 | 13,414 | 12,783 |
| 30 | 20,930 | 19,600 | 18,392 | 17,292 | 16,289 | 15,372 | 14,534 | 13,765 |
| 35 | 23,145 | 21,487 | 20,000 | 18,664 | 17,461 | 16,374 | 15,391 | 14,498 |
| 40 | 25,103 | 23,115 | 21,355 | 19,793 | 18,401 | 17,159 | 16,045 | 15,046 |
| 45 | 26,833 | 24,519 | 22,495 | 20,720 | 19,156 | 17,774 | 16,548 | 15,456 |
| 50 | 28,362 | 25,730 | 23,456 | 21,482 | 19,762 | 18,256 | 16,932 | 15,762 |
| 100 | 36,614 | 31,599 | 27,655 | 24,505 | 21,950 | 19,848 | 18,096 | 15,618 |

(**19**) En la construcción de obras y sus mejoras ó refacciones se acostumbra agregar al costo y gastos ordinarios de conservación y reparaciones : 1.° El interés del costo de la obra; 2.° Un márgen por depreciación, y algunas veces : 3.° Una anualidad que forme un fondo de reserva ó previsión para extinguir la deuda contraída por la construcción. La capitalización, del total anual de gastos así obtenido, se considera como el verdadero costo de la construcción. Todos los elementos del costo se reducen así á una base común y se hacen verdaderamente comparables.

(**20**) Así se estimó en 1889 el costo de las mejoras hechas al acueducto de Filadelfia, la rata $r$ del interés, se hizo al 3%, la depreciación se calculó como se expresa más abajo. Bajo el nombre de « Duración » se aprecia el tiempo que puede durar en buen servicio, cada elemento de la construcción, aparatos, etc., y como « Anualidad » la suma que se aparta anualmente para reemplazar, al destruirse cada $1,000 en objetos deteriorados.

| Valor actual | Anualidad | | Valor actual | | Anualidad | |
|---|---|---|---|---|---|---|
| * Porque, W | : $1.00 | :: | $1.00 | : | $p$. | Así $p = \frac{1}{W}$. |
| Ecuación (4) | | | Ecuación (5) | | | |
| Anualidad | Monto de la suma | | Anualidad | Monto de la suma | | |
| † Porque, $r$ : | $(1+r)^n - 1$ :: | | $p'$ . | $1.00. | Así, $p' = \frac{r}{(1+r)^n - 1}$ | |

‡ *Informe de* Rudolph Hering, S.M. Gray y J. M. Wilson.

| Construcción, aparatos, etc. | Duración en años. | Anualidad $ |
|---|---|---|
| Conductos de mampostería, lechos de filtros, receptáculos. | Indefinida | 0.00 |
| Edificio | 100 | 1.65 |
| Tuberías de hierro, rieles, etc. | 80 | 3.11 |
| Tubos de acero, válvulas, compuertas, etc. | 35 | 16.54 |
| Máquinas y bombas | 30 | 21.02 |
| Calderas, planta eléctrica, tranvías, equipo | 20 | 37.22 |
| Líneas telefónicas, aparatos, etc. | 10 | 87.24 |

**(21)** Sobre estas bases, se calcularon dos proyectos, capaces cada uno de suministrar 450 millones de galones (1,705,500 metros cúbicos) por día. Se los comparó así:

**Agua sin filtrar, por acueductos.**

| | | |
|---|---|---|
| *Primer costo.* | | |
| Receptáculos de depósito | | $30,900,000 |
| Acueductos | | 47,730,000 |
| Distribución | | 3,555,000 |
| Estanques distribuidores | | 1,000,000 |
| Total | | $83,185,000 |
| *Por año.* | | |
| Interés sobre $83,185,000 | | $2,495,550 |
| Depreciación | | 198,640 |
| *Manipulaciones y sostenimiento.* | | |
| Análisis é inspección | $41,61 | |
| Reparaciones ordinarias | 49,150 | |
| Bombas, salarios, etc. | 140,770 | |
| | | 231,540 |
| | | $2,925,730 |

**Agua de río tomada dentro de los límites de la ciudad y filtrada.**

| | | |
|---|---|---|
| *Primer costo.* | | |
| Filtros | | $23,174,680 |
| Canales | | 10,980,000 |
| Total | | $34,154,680 |
| *Por año.* | | |
| Interés sobre $34,154,680 | | $1,024,640 |
| Depreciación | | 205,540 |
| *Manipulaciones y sostenimiento.* | | |
| Bombas | $1,216,021 | |
| Filtración | 525,600 | |
| | | 1,741,621 |
| | | $2,971,801 |

Se observa que, no obstante que el primer costo del proyecto por filtro es mucho menor de la mitad del proyecto por acueducto, la proporción que hay que cargar por sus elementos más fácilmente destructibles, es algo mayor; al mismo tiempo, la manipulación y sostenimiento es más de 7 veces mayor, y el total de su gasto anual un poco mayor.

**Tabla 4. — Anualidad para amortizar** $1,000. (Véase ecuación 6.)

| | A interés compuesto. | | | | | | | |
|---|---|---|---|---|---|---|---|---|

## SISTEMA DUODECIMAL

(1) En el sistema árabe, se toma 10 como base, pero en el duodecimal, la base es 12 ó una « docena ». 10 es divisible sólo por 5 y por 2; y 12 es divisible dos veces por 2; y una por 3, por 4 y por 6. Esta es la razón de la popularidad de la docena como base de numeración; en los pesos como en la libra de Troy de 12 onzas; en las longitudes como en el pie en 12 pulgadas; en el año en 12 meses; en la mitad del día en 12 horas y en la moneda, en el chelín inglés en 12 peniques.

(2) **Duodecimales.** En este sistema se mide el lado de los rectángulos en pies y pulgadas; y las áreas, al multiplicar una dimensión por otra vienen en pies cuadrados y doceavos de pie cuadrado (que equivale á 12 pulgadas cuadradas, puesto que el pie tiene 144 pulgadas cuadradas) y en pulgadas cuadradas; pero los lados deben tomarse en pies y décimos de pie y en la multiplicación, así más práctica, se puede reducir la fracción decimal de los pies á pulgadas cuadradas multiplicándola por 144.

**Tabla de números inversos.** (Véanse las explicaciones después de las tablas.)

| No. | Inverso. | No. | Inverso. | No. | Inverso. | No. | Inverso. |

## NÚMEROS INVERSOS

(a) **El inverso de un número es** el número que resulta de dividir la unidad por el número de que se trata. Si $n$ es un número cualquiera, el inverso de $n = \frac{1}{n}$. Así, el inverso de $40 = \frac{1}{40} = 0.025$; inverso de $0.4 = \frac{1}{0.4} = 2.5$, etc.

Por consiguiente inver de $\frac{a}{b} = \frac{b}{a}$ porque el inver de $\frac{a}{b} = 1 \div \frac{a}{b} = 1 \times \frac{b}{a} = \frac{b}{a}$.

Como una yarda es=36 pulgadas, 1 pulgada es $= \frac{1}{36}$ de yarda=0.027777778 de yarda, por tanto el inver de 36 es=0.027777778. Asimismo una columna de agua de un pie da una presión de 0.4335 libras por pulgada cuadrada. Por consiguiente una presión de una libra por pulgada cuadrada corresponde á una columna de $\frac{1}{0.4335}$ pies=2.306805. El inver de 0.4335 es 2.306805. (Véase **h** más abajo.)

(b) Se deduce que si cualquier número en la columna encabezada « No. » es el denominador de una fracción cuyo numerador es 1, el inver correspondiente es el valor de esa fracción expresado en decimales *. Así $\frac{1}{32} = 0.03125$. Por consi-

* Los números 2 y 5 y sus potencias y productos son los únicos cuyos inver pueden expresarse en decimales exactas.

guiente **para reducir una fracción ordinaria á decimal** : multiplíquese el inver del denominador por el numerador. Así $\frac{17}{32} = 0.53125$ porque el recíproco de 32 es=0.03125 y 0.03125×17 es=0.53125.

(c) Viceversa, si el inver de un número $n$ se toma como número, el número $n$ mismo viene á ser el inver. De otro modo : el inver de $\frac{1}{n} = n$. Así, el inver de $0.205 = \frac{1}{40}$ es 40; el inver de $2.5 = \frac{1}{0.4}$ es 0.4, etc., etc.

(d) El producto de cualquier número por su inver es igual á la unidad, es decir $n \times \frac{1}{n} = \frac{n}{n} = 1$.

(e) Por consiguiente **para evitarnos el trabajo de dividir** podemos multiplicar el dividendo por el inver del divisor, puesto que $\frac{a}{n} = a \times \frac{1}{n}$.

Ej. : 200÷48750=200×inver de 48750=200×0.00002051282 (véase **h** más abajo)=0.004102564.....

(f) Cualquier número $a \div$ por el inver de un número, $n$ es $= a \div \frac{1}{n} = an$. Por consiguiente $a \div$ inver de $a$ es $= a \div \frac{1}{a} = a \times \frac{a}{1} = a^2$. Así el inver de 2 = 0.5 y $\frac{2}{\text{inver } 2} = \frac{2}{0.5} = 4 = 2^2$.

(g) Los números en la tabla anterior se extienden desde 1 hasta 1,000, pero los inver **de los múltiples de estos números por 10** pueden deducirse de la tabla agregando un cero entre la coma y la primera cifra decimal por cada cero agregado al número. Así :

Inver 390=0.002564103
— 3,900=0.0002564103.
— 39,000=0.00002564103.

Y los inver de los **números que contengan decimales** pueden deducirse de la tabla corriendo la coma en el inver de la tabla un lugar hacia la derecha por cada cifra decimal que contenga el número. Así :

Inver 227 = 0.004405286
— 22.7 = 0.04405286
— 2.27 = 0.4405286
— 0.227 = 4.405286
— 0.0227=44.05286

(h) El inver **de un número de más de tres cifras** puede tomarse de la tabla aproximadamente por interpolación. Así para encontrar el inver de 236.4

Inver de 236=0.004237288
— de 237=0.004219409
Diferencias : 1, 0.000017879; 236.4 — 236=0.4.
Luego 0.4×0.000017879=0.000007152
el inver de 236=0.004237288
menos 0.000007152
=Inver de 236.4=0.004230136 por interpolación.

El inver exacto es 0.004230118.

(i) Los inversos de los números que no están en la tabla pueden encontrarse **por medio de logaritmos**. Así, para encontrar el inver $= 236.4 = \frac{1}{236.4}$.

Log 1 =0.000000
Réstese el Log 236.4=2.373647
$\bar{3}.626353$=Log 0.00423012
Inver 236.4=$0.0042301^2$

Para encontrar el inver de $\frac{8424}{236.4} = \frac{236.4}{8424}$.

Log 236.4 = 2.373647
Réstese el Log 8424 = 3.925518

$\bar{2}.448129$ = Log de 0.0280627

Inver $\frac{8424}{236.4} = 0.0280627$.

(j) Para los números 10, 100, 1,000, etc., el puesto que ocupa á la derecha de la coma la primera cifra significativa en el número inver correspondiente es igual al número de ceros que contiene el número; pero para todos los otros números es gual al numero de cifras de la parte entera de la fracción. Así inver de 143.7 = = 0.0069....., etc. En este caso el número de cifras en la parte entera (143) es 3 y la primera cifra significativa (6) del inver 0.0069 ocupa el tercer puesto

## Raíces cuadradas y cúbicas de los números de 0.1 á 28.

Sin errores.

**Para encontrar el cuadrado ó cubo de cualquier número entero que termina en ceros.** Primero, suprímanse los ceros. Búsquese, en la tabla, el cuadrado ó cubo, según sea el caso, del número sin los ceros. Si es cuadrado agréguense después dos ceros, por cada uno de los que tenía el número y tres si es cubo. Ej., 90500 ; $905^2$=819025. Agréguense 2 veces 2 ceros; se obtiene : 81902500000. Para 90500; $905^4$=741217625; agréguense 3 veces dos ceros; se obtiene : 741217625000000.

## Raíces cuadradas y cúbicas de los números 1,000 á 10,000.

Sin errores.

**Para encontrar las raíces cuadradas ó cúbicas de números grandes, que no están contenidos en la columna de números de la tabla, se procede así :**

Dichas raíces pueden ser algunas veces tomadas de la tabla directamente, considerando como columnas de números las columnas de las potencias, y las de los números como las de raíces. Así, si se desea la raíz cuad de 25281, búsquese primero ese número en la columna de los cuadrados y frente á él en la columna de los números está 159 que es su raíz cuadrada. Para la raíz cúbica de 857375, búsquese este número en la columna de los cubos y opuesto á él, en la columna de los números, está 95, que es su raíz cúbica. Cuando no está contenido, en la columna de los cuads ó cúbs, el número exacto, podemos usar en su lugar el número más cercano á él, si no se requiere grande exactitud; pero cuando ésta es requerida se emplean los métodos siguientes :

### Para la raíz cuadrada.

Esta regla es aplicable tanto á los números enteros como á aquellos que son decimales en parte. Primero tómese de la tabla y de la manera explicada el número más cercano al número dado, también su raíz cuadrada; multiplíquese este número de la tabla por 3 y agréguese al producto el número dado. Llámese la suma A. Multiplíquese entonces el número dado por 3, agréguese al producto el número de la tabla y llámese la suma B. Entonces

A : B : : la raíz de la tabla : la raíz requerida.

Ej. : Supongamos que el número dado sea 946.53. Encontramos, en este caso, que el número más cercano de la tabla es 947 y su raíz cuad en la tabla 30.7734. Por consiguiente

$$\left.\begin{array}{l} 947 \\ 3 \\ \hline 2841 \\ 946.53 = \text{núm dado.} \\ \hline 3787.53 = \text{A.} \end{array}\right\} \text{ y } \left\{\begin{array}{l} 946.53 = \text{núm dado.} \\ 3 \\ \hline 2839.59 \\ 947 = \text{núm de la tabla.} \\ \hline 3786.59 = \text{B.} \end{array}\right.$$

Entonces A B raíz de la tabla. raíz que se busca.

3787.53 : 3786.59 : : 30.7734 : 30.7657+

Si se extrae la raíz exactamente es también 30.7657 +.

### Para la raíz cúbica.

Esta regla es aplicable tanto á números enteros como á los que tienen una parte decimal. Tómense primero en la tabla el número más cercano al número dado y su raíz cúbica; multiplíquese este número de la tabla por 2, agréguese al producto el número dado y llámese la suma A. Multiplíquese entonces el número dado por 2 y agréguese al producto el número de la tabla y llámese la suma B. Entonces

A : B : : la raíz de la tabla : la raíz que se busca.

Ej. : Supongamos que el número dado sea 7,368. Encontramos, en este caso, que el número de la tabla más cercano (en la columna de cubos) es 6,859 y su raíz cúbica, 19. Por consiguiente

$$\left.\begin{array}{l} 6859 = \text{núm de la tabla.} \\ \quad 2 \\ \hline 13718 \\ \quad 7368 = \text{núm dado.} \\ \hline 21086 = \text{A.} \end{array}\right\} \text{y} \left\{\begin{array}{l} 7368 = \text{núm dado.} \\ \quad 2 \\ \hline 14736 \\ \quad 6859 = \text{núm de la tabla.} \\ \hline 21595 = \text{B.} \end{array}\right.$$

| A | | B | | raíz de la tabla. | | raíz que se busca. |
|---|---|---|---|---|---|---|
| 21,086 | : | 21,595 | : : | 19 | : | 19.4585 |

La raíz extraída algebraicamente es 19.4588. El ingeniero rara vez necesita mayor grado de exactitud, por tanto es preferible este procedimiento al procedimiento laborioso ordinario.

### Para encontrar la raíz cuadrada de una fracción decimal.

Muy simple y exacto hasta la tercera cifra inclusive. Si el número no contiene, por lo menos cinco cifras, *contando desde la primera cifra significativa inclusive*, agréguense uno ó más ceros á fin de hacer cinco; si después de esto el número total no se puede separar de dos en dos cifras, agréguese otro cero á fin de poderlo hacer. Comenzando entonces por la primera cifra significativa é incluyéndola, se supone que el número es entero. Se busca en la tabla el número más cercano á éste; se toma su raíz cuadrada en la tabla y se corre el punto en esta raíz de la tabla, hacia la izquierda, tantos lugares cuantas cifras haya en la mitad de las cifras decimales del número modificado como se dijo.

Ej. : ¿Cuál es la raíz cuadrada de la fracción decimal 0.002? En este caso, con el objeto de tener, por lo menos, cinco cifras decimales, contando desde la primera cifra significativa (2) é incluyéndola, agréguense ceros así : 0.00.20.000 ; pero como no se pueden separar de dos en dos, agréguese otro cero así: 0.00.20.00.00. Comenzando entonces par la cifra significativa (2), supóngase que el numero es : 200000. El más cercano á éste en la tabla es 199809 y la raíz cuadrada de éste es 447. El número decimal, modificado, fué : 0.00.20.00.00; tiene ocho cifras; la mitad, cuatro; córrase por tanto el punto en la raíz 447 cuatro lugares hacia la izquierda : haciéndolo 0.0447. Esta es la raíz cuadrada de 0.002, exacta hasta la tercera cifra inclusive.

**Encontrar la raíz cúbica de una fracción decimal.** Muy simple y exacta hasta la tercera cifra. Si el número no contiene por lo menos cinco cifras á contar de la primera significativa inclusive, agréguense uno ó más ceros para formar cinco; si después de esto el número no se puede separar de tres en tres, agréguense uno ó más ceros para poderlo hacer, comenzando entonces por la primera cifra significativa inclusive y se considera el número desde ella á la derecha. Se buséa en la tabla el número más cercano á éste; se toma su raíz cúbica en la tabla y se corre el punto hacia la izquierda tantos lugares cuantas cifras haya en la tercera parte de las que contiene el número modificado.

Ej. : ¿Cuál es la raíz cúbica de la fracción decimal 0.002? En este caso, con el objeto de tener, por lo menos, cinco cifras decimales, contando desde la primera cifra significativa (2), agréguense ceros así : 0.002.000.0, pero como no se pueden separar de tres en tres, agréguense dos ceros más así 0.002.000.000. Considerando entonces desde la primera cifra significativa (2) supóngase que el número es : 2.000.000. El cubo más cercano de este número en la tabla en la columna de los cubos es 2000376 y su raíz cúbica es 126. El número decima

tal como se modificó finalmente es : 0.002000000; tiene nueve cifras, la tercera parte es 3; córrase por tanto el punto en la raíz 126 tres lugares hacia la izquierda, lo que da : 0.126. Esta es la raíz cúbica requerida de la decimal 0.002, exacta hasta la tercera cifra inclusive.

## Raíces quintas y quintas potencias.

## Raíz cuadrada de la quinta potencia de los números.

$\sqrt{n^5}$, ó potencia 5/2 de los números, $n$.

(Véase la tabla siguiente.)

La columna encabezada 12 $n$, facilita el uso de la tabla en los casos, por ej., en que la cantidad está dada en *pulgadas* y cuando se desea obtener la potencia $^5/_2$ de la misma cantidad en *pies*. Supongamos, por ej., que se tengan tubos de ½ pulg. y que se desee la potencia $^5/_2$ del diámetro en pies. Encuéntrese $^5/_2$ (diám. en pulg) en la columna 12 $n$, opuesto á éste en la colum. $n$ está 0.041666 (diám en pies) y en la columna $n$ $^5/_2$, 0.00035 (la potencia $^5/_2$ del diám. 0.041666 en pies).

Los valores de $n$ que terminan en 0 ó en 5 son exactos. Todos los otros terminan en decimales que se repiten, por ej., $n$=0.052083 significa que $n$= 0.05208333.....

---

*N. del T.* — Cuando el diámetro del tubo se tenga en *centímetros* ó *decímetros*, ó *metros*, ó cualquiera de sus fracciones, sirve esta misma tabla para encontrar las respectivas « raíces cuad de las quintas potencias » prescindiendo de la columna 12 $n$ y cuando sólo las columnas de los números $n$ y la de los $n^{\frac{5}{2}}$.

## Raíces cuadradas de la quinta potencia de los números.

(Véase la explicación anterior.)

## LOGARITMOS

(**1**) Las tablas de logaritmos facilitan mucho las operaciones de la multiplicación, división, elevación á potencias y extracción de raíces de los números *.

(**2**) Las tablas, pgs 82 á 95, contienen los logaritmos **vulgares, decimales** ó **de Briggs** de los números. El logaritmo *vulgar* de un número es el exponente de la potencia de 10 que produce el número. Véase (18). Ej., $1{,}000 = 10^{?}$ y log 1,000 (logaritmo de 1,000) = 3.00 000. Del mismo modo $28.7 = 10^{1.45\ 788}$, y log 28.7 = 1.45 788.

(**3**) En general sean A y B dos números cualesquiera y $k$ un exponente cualquiera. Se tendrá :

$$(1)\ \text{Log } AB = \log A + \log B; \qquad (2)\ \text{Log } \frac{A}{B} = \log A - \log B;$$

$$(3)\ \text{Log } A^k = k\ (\log A); \qquad (4)\ \text{Log } \sqrt[k]{A} = \frac{\log A}{k}$$

ó bien expresado en lenguaje vulgar : (1) El log de un producto = á la suma de los logs de sus factores; (2) el log de un cociente = al log del dividendo — log del divisor; (3) el log de una potencia = al log del número multiplicado por el exponente; (4) el log de una raíz = al log del número dividido por el exponente.

(**4**) De lo dicho se deduce que :

| | |
|---|---|
| Log 100 = log $10^2$ = 2.00 000 | Log 0.1 = log $10^{-1}$ = $\bar{1}$.00 000 + |
| Log 10 = log $10^1$ = 1.00 000 | Log 0.01 = log $10^{-2}$ = $\bar{2}$.00 000 |
| Log 1 = log $10^0$ = 0.00 000 + | Log 0.001 = log $10^{-3}$ = $\bar{3}$.00 000 |

(**5**) Cada log vulgar es un número mixto, compuesto de una parte *entera* que precede al punto decimal y que se llama la **característica** ó **índice** y de una fracción que sigue al punto decimal, llamada **mantisa**. Las tablas dan solamente la mantisa de cada log; la característica se encuentra como lo indicaremos después. La mantisa es siempre positiva. La característica es igual al número que representa el puesto que ocupa la primera cifra significativa, contando desde el puesto de las *unidades* como *cero;* y es positivo para todos los números mixtos y negativo para las fracciones. Ej. :

$$\underset{4\ 3\ 2\ 1\ 0}{\text{Log } 2\,4\,6\,0\,0} = \bar{4}.39\,094; \qquad \underset{0\ 1\ 2\ 3\ 4}{\text{Log } 0.0\,0\,0\,0\,4} = \bar{5}.60\,206.$$

Por ejemplo :

| | |
|---|---|
| Log 2,870 = 3.45 788 | Log 0.287 = $\bar{1}$.45 788 + |
| Log 287 = 2.45 788 | Log 0.0287 = $\bar{2}$.45 788 |
| Log 28.7 = 1.45 788 | Log 0.00287 = $\bar{3}$.45 788 |
| Log 2.87 = 0.45 788 | Log 0.000287 = $\bar{4}$.45 788 |

Debemos advertir (y compruébese en los ejemplos últimos) que la mantisa permanece la misma para cualquier número expresado por las mismas cifras significativas, cualquiera que sea la situación del punto decimal, la posición de este punto sólo afecta al valor de la característica.

(**6**) Divídase el número en 2 factores de manera que uno sea una potencia entera de 10 y el otro resulte mayor que uno pero menor que 10. Entonces el exponente ó índice de la potencia de 10, es la característica del log y el log del otro factor es la mantisa. Ej. : $2{,}870 = 1{,}000 \times 2.87 = 10^3 \times 2.87$ y el logaritmo de 2,870 (3.45 788) es la suma del exponente 3 y del logaritmo de 2.87 que es 0.45 788.

---

* Por no ser los logaritmos cantidades exactas, las operaciones que se ejecutan con ellos, están sometidas á cierta inexactitud, sobre todo cuando se mult, á un log por un número grande, puesto que entonces el error del log se mult tambien. Los log de sólo cinco decimales en la mantisa son suficientes para cálculos con números enteros de 4 ó 5 cifras. Es claro que hay más exactitud con tablas que den los logs hasta la séptima decimal.

† $\text{Log } 1 = \log \frac{10}{10} = \log 10 - \log 10 = 1 - 1 = 0$; ó bien $1 = 10^0$.

$\text{Log } 0.1 = \log \frac{1}{10} = \log 1 - \log 10 = 0 - 1 = \bar{1}.0$; ó bien $0.1 = 10^{-1}$.

‡ 0.287 = 2.87 ÷ 10. Por tanto log 0.287 = log 2.87 — log 10 = 0.45788 — 1, lo que se ha convenido en escribir así : $\bar{1}$.45 788. Véase (16). Del mismo modo log 0.0287 = log 2.87 — log 100 = 0.45 788 — 2 = $\bar{2}$.45 788.

(7) **Para encontrar el log de un número.** La tabla corta en las pags 80, 81, dan los logs de los números hasta 1,000. Todas las tablas pags 80 á 93 dan

(1) La mantisa para cada número de..... 1,000 á 1,750
(2) La mantisa para los números pares..... 1,750 á 3,750
(3) La mantisa para los quintos números de.... 3,750 á 10,000

(8) Los logs de **los números intermedios** á los que da la tabla se encuentran por simple proporción. El procedimiento está explicado en los ejemplos que se dan en conexión con las tablas, pero generalmente basta, en cuanto á exactitud, con tomar el del número más próximo en la tabla sin hacer interpolaciones.

El **antilogaritmo** es el **número** correspondiente á un logaritmo dado. Ej., log 2=0.30 103; y el antilogaritmo de 0.30 103=2. Habitualmente se escribe « $\log^{-1}$ 0.30 103=2 ».

(9) **Multiplicación.** Para multiplicar dos ó más números entre sí, súmense sus logs y búsquese el antilog de la suma. — Véase proporción (11) más abajo.

(10) **División.** Réstese del log del dividendo, el del divisor y búsquese el antilog del residuo. — Véase (11).

El inverso de cualquier número, $n$, $= \frac{1}{n}$. Véase pág. 54. Ej., inverso de $2 = \frac{1}{2} = 0.5$. Por tanto log del inverso de $n = \log \frac{1}{n} = \log 1 - \log n = 0 - \log n$.

Del mismo modo : log del inverso de $\frac{m}{n} = \log \frac{1}{m \div n} = 0 - \log \frac{m}{n}$. Ej., $\log \frac{6.3023}{23057} = 0 - \log \frac{23057}{6.3023} = 0 - 3.56\ 331 = \bar{4}.43\ 669$. Por tanto $n^{2-1} = n^1 = \frac{n^2}{n}$ $n^{1-1} = n^0 = \frac{n}{n} = 1$, $n^{0-1} = n^{-1} = \frac{1}{n}$, y $n^{0-2} = n^{-2} = \frac{1}{n^2}$ de donde se sigue que $\log n^{-1} = \log \frac{1}{n}$ = al log del inverso de $n$; $\log n^{-2} = \log \frac{1}{n^2} = \log$ del inverso de $n^2$, etc.

(11) **Proporción.** Ej., 6.3023 : 290.19=1260.7 : ?

| | | |
|---|---|---|
| Múltipl números. Súmense logs | Log 290.19 | =2.46 269 |
| | Log 1260.7 | =3.10 062 |
| | Log 290.19×1260.7 | =5.56 331 |
| Divídanse núm. Réstense logs. | Log 6.3023 | =0.79 950 |
| | Log 58,051 | =4.76 381 |

El verdadero valor es : 58049.05+.

(12) En vez de restar el log del divisor agréguese su **cologaritmo** ó **complemento aritmético** que es el log del inverso del divisor = 0 — log divisor = 10 — log divisor — 10. Ej. :

$$\frac{1523}{3.332 \times 8.655} = ?$$

| | |
|---|---|
| Log 1523 | = 3.18 270 |
| Colog 3.332=10 — log 3.332 — 10=10 — 0.52 270 — 10= | 9.47 730 — 10 |
| Colog 8.655=10 — log 8.655 — 10=10 — 0.93 727 — 10= | 9.06 273 — 10 |
| Suma de logs y cologs | =21.72 273 — 20 |
| | =Log 52.813= 1.72 273 |

El verdadero valor es : 52.8114+.

(13) Para encontrar **las potencias de los números.** Multiplíquese el log del número por el exponente de la potencia y búsquese el antilog del producto. Ej. : $36^3$=?

Log 36=1.55 630; 1.55 630×3=4.66 890. Antilog. 4.66 890=46656.

(14) Para encontrar las raíces de los números, se *divide* el log del número por el exponente de la raíz y se busca el antilog del cociente. Ej. :

$\sqrt[3]{46656}$ =? Log 46656 = 4.66 890. 4.66 890 ÷ 3= 1.55 630. Antilog 1.55 630=36

**(15) Potencias y raíces de fracciones. Características negativas.** Téngase presente que la *mantisa* es siempre positiva. Ej. (Log 0.048 = 2.68 124 = 0.68 124 — 2).

(1) $0.048^{1.5} = ?$

$1.5 \times (0.68\ 124 - 2) = 1.02\ 186 - 3 = \bar{2}.02\ 186 = \log 0.01052 = \log 0.048^{1.5}$.

(2) $\sqrt[3]{0.0048} = ?$ $\bar{3}.68\ 124 \div 3 = \bar{1}.22\ 708 = \log 0.1687 = \log \sqrt[3]{0.0048}$.

(3) Pero si la característica negativa no es exactamente divisible por el exponente, la división dará resultados erróneos; en estos casos, agréguese y réstese a lo cualquier múltiplo del exponente mayor que la característica. Ej. $\sqrt[3]{.00048} = ?$

Log 0.00048 = $\bar{4}.68\ 124 = 6 + \bar{4}.68\ 124 - 6$

$= 2.68\ 124 - 6$

Dividiendo por 3 $\quad 0.89\ 375 - 2$

$= \bar{2}.89\ 375 \quad = \log 0.0783 = \log \sqrt[3]{0.00048}$.

**(16)** Para evitar inconvenientes con el uso de las **características negativas** se acostumbra **modificarlas**, agregándoles 10 unidades y después se deduce de la suma de los logs tantas veces 10 cuantas veces se agregó. Ej. : Multiplicando ó dividiendo 7425 por 0.25, se tiene

| | Multipl. | Dividiendo. |
|---|---|---|
| Log 7425 | = 3.87 070 | =3.87 070 |
| Log 0.25 | = $\bar{1}$.39 794 | =$\bar{1}$.39 794 |
| | 3.26 864 | 4.47 276 |
| ó bien Log 7425 | = 3.87 070 | =3.87 070 |
| Log modificado de 0.25 | = 9.39 794 — 10 | =9.39 794 — 10 |
| | 13.26 864 — 10 | =$\bar{6}$.47 276 + 10 |
| | = 3.26 864 | =4.47 276 |

En muchos casos puede olvidarse la sustracción de las decenas agregadas, pero por la naturaleza de estos cálculos, el aumento producido por el olvido es tan grande que difícilmente puede pasar inadvertido.

**(17) Para dividir un log modificado** agréguesele tal múltiplo de 10 que resulte la suma excediendo al verdadero log en 10 veces el divisor. Ej. : para dividir el log 0.00048 por 3. Log 0.00048 = 4.68 124, que dividido por 3, = 2.89 375. Véase (15).

| | |
|---|---|
| Log 0.00048 | = $\bar{4}.68\ 124$ |
| Log modificado 0.00048 | = $\bar{6}.68\ 124 - 10$ |
| Agregando | $2 \times 10 = 20 \quad - 20$ |
| Dividiendo por | 3) $\bar{26}.68\ \bar{124} - 30$ |
| Se obtiene | $8.89\ 375 - 10 = \bar{2}.89\ 375$. |

**(18)** Excepto 1, cualquier número puede ser la base de un sistema de logaritmos. La base de los logs llamados **hiperbólicos** ó **Neperianos** ó **naturales**, muy usados en ingeniería naval, es

$$1 + \frac{1}{1} + \frac{1}{1 \times 2} + \frac{1}{1 \times 2 \times 3} + \frac{1}{1 \times 2 \times 3 \times 4} + \ldots = 2.71\ 828 +$$

y se los llama $e$ (epsilon) ó *e*.

$M = \log_{10} e$ (log vulgar de *e*) = 0.43 429; $\frac{1}{M} = \log_e 10$ (log hiper de 10) = 2.30 259

Para cualquier número *n*,

$$\log_e n = \frac{\log_{10} n}{M} = 2.30259 \times \log_{10} n; \quad \log_{10} n = M \log_e n = 0.43429 \log_e n.$$

**(19)** Cualquiera que sea la base elegida para un sistema de logs, la mantisa del log de cualquier número guarda una **relación constante** con la de cualquier

otro. Ej.: En cualquier sistema de logs el log 4 es siempre $2 \times \log 2$, igual $^2/_3 \times \log 8$, etc., etc.

(20) **El logaritmo del seno, tangente**, etc., de los ángulos es el log del número que representa el seno, tangente, etc., de esos ángulos. Ej.: seno de 30° = 0.50000 y el log sen 30° = log 0.50000 = 1.69897, comúnmente escrito 9.69897 — 10 ó simplemente 9.69897.

Véanse las **tablas logarítmicas** de los senos, tang., etc., pags 151, etc.

(21) Como ninguna potencia de un número positivo puede ser negativa, los números negativos propiamente no tienen log, pero **las operaciones con números negativos** pueden no obstante practicarse con logs, tratando todos los números como si fueran positivos, teniendo cuidado de usar el signo adecuado + ó — en el resultado. Por ejemplo, si se busca la 3.ª potencia de — 2). Log. 2 = 0.30 103; y $3 \times 0.30\ 103 = 0.90\ 309 = \log 8$; pero $(-2)^3$ debe ser negativo, por tanto $(-2)^3 = -8$.

## Carta y regla logarítmica.

(1) Por medio de una carta ó diagrama se hacen gráficamente las operaciones logarítmicas y mecánicamente, por medio de una regla corrediza *. No obstante, con este sistema y aun con cartas amplias y buenas reglas no se logra exactitud más allá de la 3.ª ó 4.ª cifra. Su uso facilita mucho los cálculos en Hidráulica y otros ramos de la Ingeniería.

(2) La **carta logarítmica** consiste primeramente en un cuadrado * sobre cuyos lados las distancias 1 — 2, 1 — 3, etc. están marcadas en relación con los logs (0.30 103, 0.47 712, etc.) de los números 2, 3, etc. Generalmente se usa el papel cuadriculado poniendo en cada línea de la cuadrícula el log correspondiente en lugar de los números. Las líneas que representan los números se trazan en sus respectivos lugares. — (Véanse las líneas de los logs y la de los números correspondientes debajo y á la izquierda del diagrama. *N. del T.)*

(3) La **regla corrediza logarítmica** consiste generalmente en 4 escalas A, B, C y D, véase (17); las escalas A y D se construyen en la regla fija, y la B y C en la lengueta ó regla movediza. Como en el diagrama las escalas son *logarítmicas*, véase (2), pero marcadas con los *números* que corresponden á los logaritmos. Las escalas A y B son iguales como lo son las C y D, pero una distancia dada en A ó B, representa un log doble del de C ó D. Véase (4). Por tanto, cada número marcado en A es el *cuadrado* del que le corresponde ó coincide en D.

(4) Una escala logarítmica simple está generalmente numerada de 1 á 10, ó de 10 á 100; pero debe tomársela como representando cualquier serie comprendida entre números representados por $10^n$ á $10^{n+1}$; como por ej. de $0.1=10^{-1}$ á $1.0=10^0$ (en que $n=-1$); ó de $1.0=10^0$ á $10.0=10^1$ (en que $n=0$) ó de 10.0 á 100 (en que $n=1$), etc. Aquí $n$ y $n+1$ son las características de los correspondientes logaritmos.

Una escala simple puede servir sin embargo para todos los valores, desde $o$ hasta el infinito; pero por conveniencia se agregan á veces varias escalas contiguas.

Cuando una línea llega al límite del cuadrado, ella continúa en el punto directamente opuesto. Por ej.: en el caso de la línea $x^{2}/_{3}(=\sqrt[3]{x^2}.)$ (Véase el diagrama.)

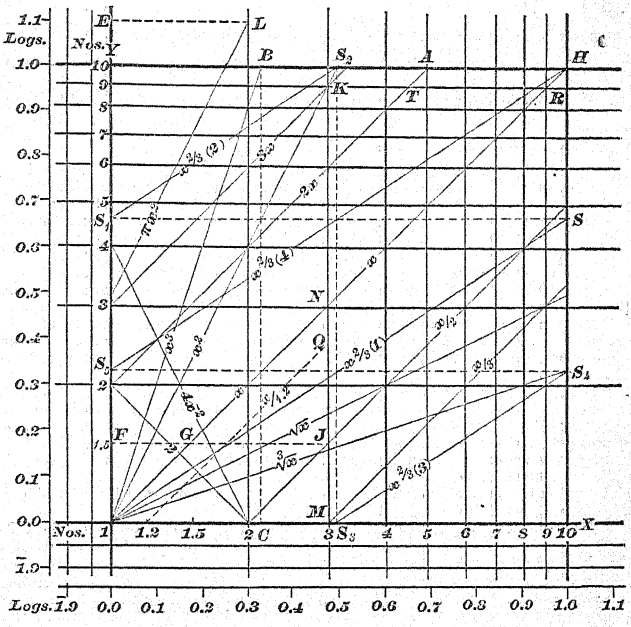
| Línea marcada $x^{2/3}$ | Entre. | Corresponde á los valores | |
|---|---|---|---|
| | | De $x$ desde. | De $x^{2/3}$ desde. |
| (1) | 1 y S | 1 á 10 | 1 á 4.64 |
| (2) | $S_1$ y $S_2$ | 10 á 31.62 | 4.64 á 10 |
| (3) | $S_2$ y $S_3$ | 31.62 á 100 | 10 á 21.54 |
| (4) | $S_3$ y H | 100 á 1000 | 21.54 á 100 |

Obsérvese que los números marcados en cualquier escala deben ser tomados como diez veces mayores que los números correspondientes de la escala inmediata anterior y la característica, en consecuencia, aumentada en 1, y viceversa. Así en el diagrama log. 1.5+log 2=distancias (1–1.5+1–2)=log 3=distancia 1–M. Pero log 15+log 20=(log 1.5+log 10)+(log 2+log 10)=(1–1.5+1–10)+(1–2+1–10), de tal manera que la característica del log que resulta está aumentada en 2, y el 3 que representa el producto de 15 y 20 está realmente en el segundo cuadrado á la derecha del de la figura. Al tratarse de las raíces de los números, recuérdese que, multiplicando ó dividiendo el número por 0.1, 10, 100, etc. (y cambiando por tanto la característica de su log) cambia también la mantisa del log de su *raíz*. Ej.: $\sqrt[3]{2.7}=1.39\ldots$ (log=0.14 379), pero $\sqrt[3]{27}=3$ (log=0.47 712) y $\sqrt[3]{270}=6.46\ldots$ (log= 0.81 023). La carta ó la regla dan *todas* estas raíces *posibles* y se debe tener buen cuidado en escoger la que

* La relación entre las mantisas de los logs de cualesquiera números, siendo constante, para cualquier sistema de logs, las relaciones entre las distancias respectivas en la carta ó en la regla corrediza, es la misma para todos los sistemas, y el uso de aquéllas es independiente del sistema de logs empleado.

conviene al caso. La mayor parte de las operaciones exceden del límite de una escala y las facilidades que puede dar el uso de estos instrumentos dependen de la habilidad en pasar fácil y prontamente de una escala á otra. Esta habilidad se alcanza por la práctica ayudada por un conocimiento completo de los principios que envuelve. Cuando se tiene que practicar una serie de operaciones distintas, se usa una marca ó indicador corredizo, que lo trae la misma regla para evitar que un movimiento de la corredera cambie lo marcado. Las reglas se venden con sus instrucciones.

(5) **Multiplicación y división.** Ej. : $2 \times 1.5 = ?$ Sobre la línea 1–X en la carta ó sobre C ó D en la regla la distancia 1–1.5 representa en escala el log (0.17 609) de 1.5 y 1–2 representa el log (0.30 103) de 2. Si se suman estas dos distancias agregándole la distancia 1–2 á la 1–1.5 sobre las 1–X de la carta ó colocando la regla C sobre la D como está en la figura, se obtiene la distancia $1\text{–}3 = 0.47\,712$ = á la mantisa del log 3 ó del log $(2 \times 1.5)$ *. Al contrario, para dividir á 3 por 2, gráfica ó mecánicamente se resta de la distancia 1–3 la 1–2.



(6) **En la carta logarítmica** por ser iguales las escalas de ambos ejes 1–X, 1–Y, la línea 1–H bisectriz y diagonal del cuadrado forma un ángulo de 45° con cada eje (tan 45° = 1), † y es también bisectriz de todos los cuadrados formados sobre coordenadas iguales. Todos los puntos de la diagonal $x$ que están sobre los 2, 3, etc. del eje 1–X corresponden á los opuestos 2, 3, etc., en el eje 1–Y. Véase (4).

* En la regla corrediza, tal como aparece, *cada* número en D = 1.5 × el número con que coincide en C.

(†) Al tratarse de las tangentes de los ángulos, en la carta logarítmica, deben tomarse las distancias sobre la escala proporcional de los logaritmos y no sobre la de los números que son de mera conveniencia; por ej.: trazando la línea 1-B se tiene que tang $\text{C1B} = \frac{\text{BC}}{\text{C1}} = \frac{1.0}{0.33}$ y no $\frac{10}{2.15}$.

**(7)** Si se trazan las líneas 2–A, 3–K, etc. (marcadas 2 $x$, 3 $x$, etc.) paralelas á 1–H y, *sobre* ella, los puntos de esas líneas situados sobre cualquier punto $x$ del eje 1–X estarán respectivamente opuestos á los números que dan el producto 2 $x$, 3 $x$, etc., sobre el eje 1–Y; así también las líneas trazadas del mismo modo, *debajo* de 1–H por los puntos 2, 3, etc. de 1–X, darán respectivamente los valores $\frac{x}{2}$, $\frac{x}{3}$, etc., en 1–Y; las líneas semejantes trazadas debajo de 1–H, por los puntos 2, 3, etc. de 1–X, dan los valores de $\frac{x}{2}$, $\frac{x}{3}$, etc. Si estas líneas $\frac{x}{2}$, $\frac{x}{3}$, etc. se prolongan hacia abajo, cortarán respectivamente á 1–Y (prolongada) en $0.5\left(=\frac{1}{2}\right)$, $0.33...\left(=\frac{1}{3}\right)$*. Véase (*4*).

**(8) Potencias y raíces.** Si se traza la línea $x^2$ por el punto 1, formando un ángulo $S_2$ 1–X cuya $\text{tang}=\frac{S_1-S_2}{S_2-1}=\frac{1}{0.5}=2$, dará valores de $x^2$. Así la vertical por 3 en 1–X corta la línea $x^2$ en un punto cuyo opuesto en 1–Y es $9=3^2$. Del mismo modo la línea $x^3$ (tang=3) da valores de $x^3$; y la línea $\left(\text{tang}=\frac{1}{3}\right)$ da valores de $x^{\frac{1}{3}}$ ó $\sqrt[3]{x}$. Véase (*4*).

**(9)** Cualquier ecuación de la forma $y=Cx^n$ en que $\log y=\log C+n \log x$ (como: área del círculo$=\pi\times$radio$^2$), está representada en una carta logarítmica por una línea recta trazada de modo que la tangente del ángulo que forme con 1–X sea$=n$ y que corte en un punto a la línea 1–Y cuyo valor represente á C. Ej.: la línea marcada $\pi x^2$ (tang$=2$) es línea de cuadrados y, habiendo sido trazada desde $\pi$ (=3.14) en 1–Y da los valores de $\pi x^2$. Así: para un círculo de radio 2, se encuentra en la línea $\pi x^2$ sobre el punto 2, un punto L cuyo opuesto E ó 12.57 es el área de dicho círculo †. Al revés, teniendo el área 12.57 se obtiene por el diagrama el radio$=2$.

**(10)** Cuando, con un diagrama se van á resolver muchas ecuaciones de una sola especie como $y=Cx^n$, en que C es un coeficiente variable y $n$ un exponente constante, trácense sobre la hoja paralelas á cortos intervalos que formen todas el mismo ángulo con 1–X.

**(11)** A cualquier log como 1–3 (=log 3), se puede substituir su igual, M–N ó 3–N, que concurren á la diagonal central 1–H marcada $x$; y, entonces, puesto que, por ej., 1–1.2=N–Q, 1–3=N–K, etc., se puede agregar cualquier log (como 1–3), moviendo *hacia arriba*, desde la línea $x$ (como de N hacia K) ó hacia *la derecha*, y *restar* cualquier log (como 1–1.2) moviendo *hacia abajo* (como de N hacia Q) ó hacia *la izquierda*.

Esto facilita la realización de una serie de operaciones. Ej.: Multipliquese $1.5\times2$ (=3) por 3 (=9) y divídase por 2 (=4.5).

F–G=1–F=log 1.5. Agréguese G–J=1–2=log 2; súmese F–J=log 3=1–3=M–N. Agréguese N–K=1–3=log 3; súma=M–K= log 9=1–9 =9– R. Réstese R–T=1–2=log 2; residuo =9–T=log. 4.5.

**(12) Exponentes negativos.** — Si la $x$ está en el divisor la línea se inclinará en opuesta dirección ó hacia abajo de izquierda á derecha. Así la línea 4–2 que parte de 4 sobre 1–Y y forma con 1–X el ángulo X, 2, 4, cuya $\text{tang}=\frac{602...}{-301...}=-2$, representa la ecuación $y=\frac{4}{x^2}=4x^{-2}$.

**(13)** Si las líneas de productos, potencias y raíces $Cx$, $x^n$, y $\sqrt[n]{x}$, etc., están trazadas con ángulos, cuyas tangentes son menores en 1 que los ángulos formados por las correspondientes líneas en nuestra figura, los resultados deben leerse directamente en las líneas oblicuas trazadas paralelas á 2–2. Las líneas ($Cx$) que

---

* En cada una de estas líneas, el producto de los dos números en sus extremos es=10. Ej.: en la línea 2–A, $2\times5=10$; en la 3–K, $3\times3.33...=10$, etc. Esto constituye una tabla de *inversos*.

(†) Con los buenos diagramas y reglas no se debe contar con exactitud más allá de tercera ó cuarta cifra.

dan múltiples y submúltiples de la primera potencia de $x$ se hacen entonces horizontales (tang=0).

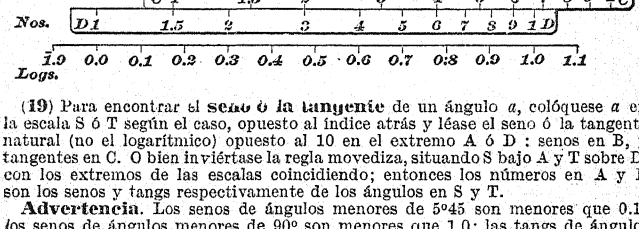
(14) **Potencias y raíces con la regla corrediza.** — Las escalas C y D por ser dobles de las escalas A y B, cuando coinciden sus extremos forman una tabla de cuadrados y raíces. Véase (3). Moviendo la parte corrediza se resuelven ecuaciones de la forma $y=(Cx)^2$, y también $y=Cx^4$. Entonces, con la regla como está cada número en A es = al cuadrado de (1.5×el número con que coincide en C); con 1 en B opuesto a 1.5 en A, cada número en A es=1.5×el cuadrado del número con que coincide en C.

(15) Como $x^3=x^2\times x$, encontramos las terceras potencias ó cubos, colocando la regla con 1 en B opuesto á $x^2$ en A (por tanto opuesto á $x$ en D), véase (3), y leyendo $x^3$ en A opuesto á $x$ en B. Ej.: $1.5^3=?$ Sitúese 1 en B opuesto 1.5 en D: por tanto opuesto $1.5^2$ (=2.25) en A. Entonces en A opuesto 1.5 en B se encuentra $3.375=1.5^3$. O bien inviértanse los extremos de la regla corrediza. Sitúese 1.5 en B opuesto 1.5 en D, y por tanto opuesto $1.5^2=2.25$ en A. Entonces agregando log 1.5 (en B) al log 2.25 en A, se encuentra 3.375 ($=1.5^3$) en A opuesto 1 en B

(16) Al contrario: para encontrar á $\sqrt[3]{x}$, se invierte la regla corrediza (á su posición normal) hasta que se encuentre en B opuesto á $x$ en A, el mismo número que se tiene en D opuesto á 1 en C y este número será $=\sqrt[3]{x}$. O bien inviértanse los extremos de la regla corrediza,* sitúese 1 en C opuesto á $x$ en A y encuéntrese, en B, un número que coincida con su igual en D; este número es $=\sqrt[3]{x}$. Véanse también (17) (18).

(17) En la parte atrás de la regla se traza generalmente una escala de logaritmos (véase la escala debajo de la regla en la figura) y dos escalas de ángulos marcadas « S » y « T » respectivamente, para encontrar los senos de los ángulos mayores que 0°34′ y tangentes de ángulos entre 5°42′ y 45°.

(18) Colocando 1 en C, opuesto á cualquier número $x$ en D (con la regla móvil en su posición normal) el log $x$ se lee en la escala de los logaritmos, por medio de un índice en la parte atrás de la regla. Deben usarse los logaritmos para encontrar potencias y raíces.



(19) Para encontrar el **seno ó la tangente** de un ángulo $a$, colóquese $a$ en la escala S ó T según el caso, opuesto al índice atrás y léase el seno ó la tangente natural (no el logarítmico) opuesto al 10 en el extremo A ó D: senos en B, y tangentes en C. O bien inviértase la regla movediza, situando S bajo A y T sobre D, con los extremos de las escalas coincidiendo; entonces los números en A y D son los senos y tangs respectivamente de los ángulos en S y T.

**Advertencia.** Los senos de ángulos menores de 5°45 son menores que 0.1; los senos de ángulos menores de 90° son menores que 1.0; las tangs de ángulos entre 5°42 y 45° están entre 0.1 y 1.0.

(20) Engrasando los filos de la regla corrediza y la cavidad donde corre, se hace más fácil su manejo, á veces incómodo. Si la regla móvil está muy floja, debe ahondarse la cavidad y colocarse, á guisa de resorte, una laminilla de acero delgada en la canal, y apoyada en la regla.

* Con la regla móvil así invertida y con los extremos de las escalas coincidiendo, los números en A y B son *inversos* (pág. 51), co.. o también los de C y D.

## LOGARITMOS DE LOS NÚMEROS HASTA 1,000.

Para el uso de los logaritmos, véanse págs 72 á 75.
Para los logs con cinco cifras de los números hasta 10,000, véanse las págs 82 á 93.

## LOGARITMOS DE LOS NÚMEROS HASTA 1,000. (Continuación.)

Para el uso de los logaritmos, véanse págs 72 á 75.
Para los logs con cinco cifras de los números hasta 10,000, véanse las págs 82 á 93.

| | | 41 | | | 39 | | | 38 | | | 36 | | | 35 |

**Ejemplo**: Encontrar el log 11826:
log 11830=07298
dif. = 10 **36**
log 11820=07262
11826 — 11820=**6**
dif. para **6** debajo de **36**=22
log 11826=
07262+22 = 07284.

**Ejemplo**: Encontrar log 12605:
log 12610=10072
dif. = 10 **35**
log 12600=10037
12605 — 12600 = **5**
dif. para **5** debajo **35**=18
log 12605=
10037+18=10055.

| | 35 | 34 | 33 | 32 | 31 | 30 | 29 | |
|---|---|---|---|---|---|---|---|---|
| **1** | 4 | 3 | 3 | 3 | 3 | 3 | 3 | **1** |
| **2** | 7 | 7 | 7 | 6 | 6 | 6 | 6 | **2** |
| **3** | 11 | 10 | 10 | 10 | 9 | 9 | 9 | **3** |
| **4** | 14 | 14 | 13 | 13 | 12 | 12 | 12 | **4** |

| **9** | 32 | 31 | 30 | 29 | 28 | 27 | 26 | **9** |

**Un guión** antes ó después de un log indica que su verdadero valor es *menor* que el tabular en *menos* de la mitad de la unidad correspondiente al último puesto. Ej.:
log 1366=1354507
log 1367=1357685

**Ejemplo**: Para encontrar log 15414:
log 15420=18808
dif. = 10 **28**
log 15410=18780
15414 — 15410=4
dif. para 4 debajo **28**
=11
log 15414=
18780+11=18791.

| | **29** | **28** | **27** | **26** | **25** | **24** | |
|---|---|---|---|---|---|---|---|
| **1** | 3 | 3 | 3 | 3 | 3 | 2 | **1** |
| **2** | 6 | 6 | 5 | 5 | 5 | 5 | **2** |
| **3** | 9 | 8 | 8 | 8 | 8 | 7 | **3** |
| **4** | 12 | 11 | 11 | 10 | 10 | 10 | **4** |
| **5** | 15 | 14 | 14 | 13 | 13 | 12 | **5** |
| **6** | 17 | 17 | 16 | 16 | 15 | 14 | **6** |
| **7** | 20 | 20 | 19 | 18 | 18 | 17 | **7** |

| **9** | 26 | 25 | 24 | 23 | 23 | 22 | **9** |

**Un guión** antes ó despues de un log indica que su verdadero valor es *menor* que el tabular en *menos* de la mitad de la unidad correspondiente al último puesto. Ej.:
log 1562=1936810
log 1563=1939590

**Un guión** antes ó después de un log indica que su verdadero valor es *menor* que el tabular en *menos* de la mitad de la unidad correspondiente al último puesto. Ej.:

log 3128 = 4952667
log 3130 = 4955443

Log 9605=9824974.

# GEOMETRIA

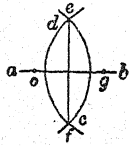
Definición de **líneas, figuras planas y sólidos.** — Hablando estrictamente, una **línea** es simplemente una longitud ó distancia. Las líneas que trazamos en el papel tienen no sólo longitud sino también anchura y espesor, sin embargo son el símbolo más conveniente que podemos emplear para designar una línea geométrica. Línea vertical es la que se dirige hacia el centro de gravedad de la tierra, y horizontal, la que corta en ángulo recto la vertical. Una figura plana es un plano encerrado por líneas rectas ó curvas que se denominan perímetro, circunferencia ó periferia. Se confunde á menudo el perímetro con la figura misma como cuando se habla de trazar círculos, cuadrados, etc., y lo que trazamos son sus perímetros. Geométricamente hablando una figura tiene longitud y latitud, pero no espesor. **Sólido** es todo lo que tiene longitud, latitud ó anchura y espesor.

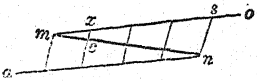
Las figuras ó sólidos semejantes no han de ser necesariamente del mismo tamaño, pero sí precisamente de la misma **forma**. Así, dos cuadrados cualesquiera son semejantes entre sí, como también dos círculos ó cubos cualquiera que sea su diferencia de tamaño. Cuando no sólo son de la misma forma sino del mismo tamaño, se dice que son **iguales**.

**Las líneas** están entre sí como sus **longitudes**, pero las áreas ó superficies de **figuras** semejantes están entre sí como los **cuadrados** de sus líneas homólogas. Los **sólidos** semejantes están entre sí como los **cubos** de sus líneas homólogas.

**Advertencia.** — Por simples que aparezcan las operaciones siguientes, se requiere gran cuidado y buenos instrumentos á fin de obtener en la práctica resultados exactos. Algunas de ellas pueden ejecutarse mucho mejor por medio de un triángulo metálico que tenga un ángulo recto. En el terreno, la cinta de agrimensor, cadena ó una percha, sustituirá á los compases de división y regla que se usan en el dibujo.

**Para dividir una línea dada** *ab* **en dos partes iguales.** — De sus extremos *a*, *b*, como centros y con cualquier radio mayor que la mitad de *ab* descríbanse los arcos *c*, *d*, y únase *e* con *f*. Si la línea *ab* es muy larga, trácense primero distancias iguales *ao*, *bg* en cada lado desde los extremos, y procédase entonces como si *og* fuera la línea que tiene que dividirse. O bien mídase *ab* para determinar su centro.





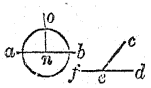
**Para dividir una línea** *mn* **en cualquier número de partes iguales.** De *mn* trácense dos líneas paralelas cualesquiera *mo*, *na*, hasta una distancia indefinida y sobre ellas desde *m*, *n* márquese el número requerido de partes iguales de una longitud cualquiera y conveniente; después únanse los puntos correspondientes así marcados. O bien trácese sólo una línea como *mo* y únase entonces *s* con *n*, trazando las otras líneas paralelas á ésta.

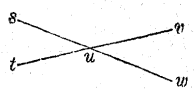
**Para dividir una línea dada** *mn* **en dos partes que deben estar entre sí en una proporción dada** se aplica el mismo principio anterior. Por ejemplo: en la proporción de 1 á 3. Trácese primero una línea cualquiera *mo* y con cualquiera apertura del compás hágase *mx* igual á una división y *xs* igual á tres de estas divisiones. Unanse *sn* y paralela á ella trácese *xc*. Entonces *mc* es á *cn* como 1 es á 3.

## ÁNGULOS

Cuando dos líneas rectas se encuentran con cualquiera inclinación, esa inclinación se llama **ángulo** y se mide por los grados contenidos en un arco de círculo que tenga por centro el punto donde se cortan las dos líneas. Como todo círculo, grande ó pequeño, se supone dividido en 360 grados, se deduce que á cualquier número de grados de un círculo pequeño corresponderán igual número en el mayor.

Cuando dos líneas rectas como *on*, *ab* se encuentran de tal manera que la inclinación *ona* es igual á la inclinación *onb*, se dice que las dos líneas son **perpendiculares** entre sí y los ángulos *ona*, *onb* se llaman **ángulos rectos** y son

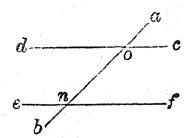


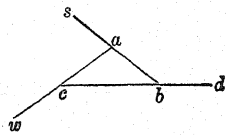


iguales á 90 grados ó á una cuarta parte de la circunferencia del círculo. Cualquier ángulo, como *ced*, más pequeño que un ángulo recto se llama **agudo** y uno *cef* mayor que un ángulo recto se llama **obtuso**. Cuando una línea encuentra otra como en la figura siguiente los dos ángulos en el mismo lado de cualquiera de las dos líneas se llaman **adyacentes**. Así : *vus* y *vuw* son adyacentes; también *tus* y *tuw*; *sut* y *suv*, *wut* y *wuv*. La suma de dos ángulos adyacentes es siempre igual á dos ángulos rectos ó á 180°. Por tanto, si conocemos el número de grados que contiene uno de ellos y lo restamos de 180° obtenemos el otro.

Cuando dos líneas rectas se cruzan formando cuatro ángulos, cualquier par de estos ángulos, situados en direcciones opuestas, se llaman **opuestos por el vértice** tales como *suv*, *tuw*. Los ángulos opuestos por el vértice son iguales.

Cuando una línea recta *ab* corta dos líneas paralelas *dc*, *ef*, los ángulos **alternos** que forman una especie de Z son iguales entre sí. Así, los ángulos *don*, *onf*, son iguales como también lo son *con*, *one*. También la suma de los dos ángulos inte-

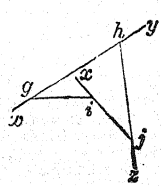




riores en el mismo lado de *ab* es igual á dos ángulos rectos ó 180°; así : *con*+*onf*=180°; también *don*+*one*=180°.

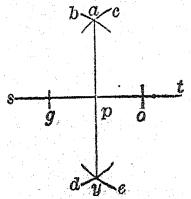
Se llaman **ángulos internos** los formados dentro de cualquier figura por la intersección de dos de sus lados como los ángulos *cab*, *abc*, *bca*, de este triángulo. La suma de los ángulos internos de un polígono de cualquier número de lados, es igual á tantas veces dos ángulos rectos menos cuatro, como lados tiene el polígono. Así, un triángulo tiene 3 lados; el doble de este número es 6, y seis ángulos rectos, ó 6×90°=540°, de los cuales se restan cuatro ángulos rectos ó 360°; y quedan 180°, que es el número de grados que suman los ángulos de un triángulo. Este principio sirve para probar las medidas hechas en los ángulos de cualquiera figura; porque si la suma de todos los ángulos medidos, no está de acuerdo con la regla anterior, es prueba de que hemos cometido error.

**Angulo externo** en un polígono, es cualquier ángulo como *abd* formado *fuera* de la figura por el encuentro de cualquier lado, *ab*, con la prolongación



del lado adyacente *bd;* lo mismo son los ángulos *cas*, *bcw*. La suma de todos los ángulos exteriores en cualquier polígono, sea cual fuere su número de lados, es igual á 360°; pero si alguno de los ángulos es *reentrante* como *gij*, el ángulo **interior** *gij* excede 180°, y el ángulo *gix* siendo = 180° — el ángulo interior es negativo. Así *abd* + *bcw* + *cas* = 360°; y, *yhj* + *zji* — *gix* + *igw* = 360°; los ángulos como *a*, *b*, *c*, *g*, *h*, *j*, cuyos vértices apuntan hacia afuera, se llaman **salientes.**

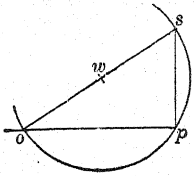
**En cualquier punto dado**, *p*, **de una línea** *st*, **levantar una perpendicular** *pa*. Tomando *p* por centro, fíjense con el compás dos distancias iguales, *po* y *pg*. Luego, tomando *o* y *g* como centros, trácense con una abertura mayor



que la mitad de *og* los dos arcos *b* y *c* y únase *a* con *p*. O todavía mejor: descríbanse cuatro arcos y únase *a* con *y*.

O de otro modo, desde *p* con cualquier escala conveniente descríbanse dos arcos pequeños *g*, *a*, cualquiera de los dos con un radio 3 y el otro con un radio 4. Entonces de *g* con un radio 5, descríbase el arco *b*. Unase *p* con *a*.

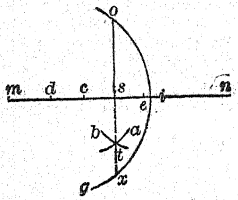
**Si el punto** *p* **está en un extremo de la línea ó muy cerca de él,**

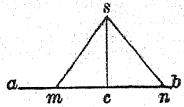


**extiéndase la línea si es posible** y procédase como arriba. Pero si esto no puede hacerse, de un punto conveniente *w*, ábrase el compás hasta *p*, y descríbase el semicírculo *spo;* por *ow* trácese *ows;* y únase *p* con *s*.

O úsese el procedimiento anterior con los radios 3, 4, 5.

**De un punto dado** *o* **bajar una perpendicular** *os*, **á una línea dada** *mn*. De *o* mídanse hasta la línea *mn* dos distancias iguales, *oc*, *oe*, y desde *c* y *e*,

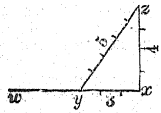


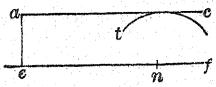


como centros, con cualquiera abertura mayor que la mitad de *ce*, descríbanse los dos arcos *a* y *b*, y únanse *ot*. O desde cualquier punto *d* sobre la línea ábrase el compás hasta *o* y descríbase el arco *og;* hágase *ix* igual *io;* y únanse *ox*.

**Si la línea**, *ab*, **está en el terreno** y se quiere levantar una perpendicular desde *c*, mídanse primero dos distancias iguales cualesquiera, *cm*, *cn*.

En *mn*, sujétense los extremos de un pedazo de cuerda, cinta de agrimensor, ó cadena, *msn*, luego átese la cuerda, etc., como se demuestra en *msn*, siendo su centro *s* y entonces *sc* será la perpendicular que se busca. Si la perpendicular *xz* debe levantarse en el extremo de la línea *wx*, mídase primero *xy* sobre la línea igual á tres unidades cualesquiera y sujetando el extremo de una cinta de agrimensor en *x*, se marcan nueve unidades en *y*; sujétese ahora la marca de cuatro unidades

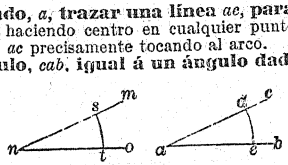




en *z* manteniendo á *zx*, *xy* igualmente tensos. Entonces *zx* será la perpendicular que se requiere porque 3, 4 y 5 forman los lados de un triángulo rectángulo. En lugar de 3, 4 y 5 se pueden usar cualesquiera múltiples de estos números, tales como 6 8 y 10; 9, 12 y 15, etc.

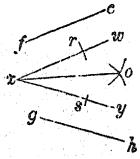
**Por un punto dado, *a*, trazar una línea *ac*, paralela á otra línea *ef*.** Descríbase un arco *t* haciendo centro en cualquier punto de la línea *ef* con la distancia *ae* y trácese *ac* precisamente tocando al arco.

**Formar un ángulo, *cab*, igual á un ángulo dado *mno*, en cualquier**



**punto, *a*, de una línea, *ab*.** Desde *n* y *a* con cualquier radio, descríbanse los arcos *st*, *de*, mídase *st*, hágase *ed*, igual á él; y por *ad*, trácese *ac*.

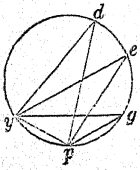
**Dividir cualquier ángulo, *wxy*, en dos partes iguales.** Trácense desde *x* dos distancias iguales cualesquiera, *xr*, *xs*, de *r*, *s*, descríbanse, con cualquier radio, dos arcos que se intercepten en *o* y únase *o* con *x*. Si los dos lados del ángulo no se cortan como sucede en *cf*, *gh*, extiéndanse hasta que se encuentren ó

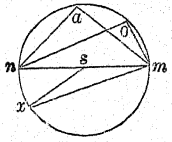


trácense líneas *xw*, *xy* paralelas y á distancias iguales de ellas de modo que se encuentren, y entonces se procederá como antes.

Todos los ángulos como *nam*, *nom*, cuyo vértice se encuentra en la circunferencia de un semicírculo y cuyos lados terminan en los extremos de un diámetro *nm*, son ángulos rectos ó como se dice generalmente: **todos los ángulos inscritos en un semicírculo son ángulos rectos.** Un ángulo *nsx* cuyo vértice está en el centro de un círculo, es dos veces mayor que un ángulo *nmx* apoyado en la circunferencia; cuando los lados de ambos comprenden el mismo arco *nx*.

Todos los ángulos, como *ydp*, *yep*, *ygp*, que están en la circunferencia de un

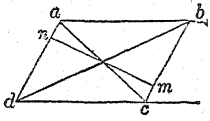




círculo y cuyos lados corresponden al mismo arco $yp$, son iguales entre sí; ó como se dice usualmente : todos los ángulos inscritos en el mismo segmento de un círculo, son iguales.

El **complemento** de un ángulo es lo que le falta para llegar á 90°. Así, el complemento de 80° es 90° — 80°=10° y el de 210° es 90° — 210° = — 120°. El **suplemento** de un ángulo es lo que le falta para llegar á 180°. El suplemento de 80° es 180° — 80°=100°; y el de 210° es 180° — 210° = — 30°. Pero generalmente podemos prescindir de anteponer los signos + ó — á los complementos y suplementos y llamar el complemento de un ángulo, su diferencia con 90° y el suplemento su diferencia con 180°.

**Ángulos de un paralelogramo.** Paralelogramo es cualquiera figura rectilínea de cuatro lados cuyos lados opuestos son iguales, como *abcd*. Cualquiera línea trazada á través de un paralelogramo, entre dos ángulos opuestos se llama *diagonal*, como *ac*, *bd*. Una diagonal divide el paralelogramo en dos partes iguales y también cualquiera línea *mn* trazada por el centro de una de las dos diagonales; además la línea *mn* misma queda dividida en dos partes iguales por la diagonal. Dos diagonales se cortan entre sí, y dividen también al paralelogramo en cuatro triángulos de iguales áreas. La suma de los dos ángulos á los extremos de uno cualquiera de los lados es=180°. Así $dab+abc=abc+bcd=180°$; y la suma de los cuatro ángulos *dab*, *abc*, *bcd*, *cda*=360°.



La suma de los cuadrados de los cuatro lados es igual á la suma de los cuadrados de las dos diagonales.

### Para reducir minutos y segundos á grados y fracciones decimales de un grado, etc.

En cualquier ángulo dado :

| | | | |
|---|---|---|---|
| **Número de grados** | = Número de minutos | ÷ | 60. |
| | = — de segundos | ÷ | 3,600. |
| **Número de minutos** | = — de grados | × | 60. |
| | = — de segundos | ÷ | 60. |
| **Número de segundos** | = — de grados | × | 3,600. |
| | = — de minutos | × | 60. |

## Tabla de minutos y segundos en decimales de un grado y de segundos en decimales de un minuto.

(Las columnas de min y gr se emplean y responden también para segundos y minutos.)

En cada equivalente **el último dígito se repite indefinidamente.**
Véase * debajo :

| Mins. | Grad. | Mins. | Grad. | Mins. | Grad. | Segs. | Grad. | Segs. | Grad. | Segs. | Grad. |

|---|---|---|---|---|---|---|---|---|---|---|---|

* Cada equivalente tiene una **decimal periódica.** Ejemplo :

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| 2 | minutos | = 0.033333..... | grados | 12 | segundos | = 0.200000..... | minuto |
| 7 | — | = 0.116666..... | — | 1 | — | = 0.000277..... | grado |
| 12 | — | = 0.200000..... | — | 50 | — | = 0.013888 ..... | — |

## MEDIDA APROXIMADA DE ÁNGULOS

**(1) Los cuatro dedos de la mano** formando ángulos rectos con el brazo y á distancia del largo del brazo de los ojos, cubren 7 grados y un ángulo de 7° corresponde como á 12.2 pies en 100 pies ó á 12.2 metros en 100 metros.

**(2) Se miden aproximadamente ángulos por medio de una regla de dos pies**, sea en un trazado ó entre objetos distantes en el terreno, así: si las puntas interiores de una regla ordinaria de dos pies de largo (articulada en su mitad, como se usa, *N. del T.*) se abren con las separaciones que indica la columna de pulgadas en la próxima tabla, las dos reglas quedarán inclinadas entre sí los ángulos que determina la columna de ángulos de la misma tabla. No se debe contar con gran exactitud en este sistema y mucho menos después que el ángulo pasa de 105°, porque el error se aumenta á proporción que se hace mayor la abertura.

Los ángulos para aberturas intermedias de aquellos que se dan, pueden calcularse por medio de una simple proporción.

**Tabla de ángulos correspondientes á aberturas de una regla de 2 pies.** (Original.)

| Pulg. | Gr | Min. | Pulg. | Gr | Min. | Pulg. | Gr | Min. | Pulg. | Gr | Min. | Pulg. | Gr | Min. | Pulg. | Gr | Min. |

**(3) Con la misma tabla usando pies en lugar de pulgadas.** De cualquier punto mídanse 12 pies hacia cada objeto y colóquense marcas, mídanse las distancias en pies entre estas marcas. Supóngase que la primera columna de la tabla esté en pies en lugar de pulgadas. Entonces frente á la distancia en pies estará el ángulo.

⅛ de pie = 1.5 pulgadas.

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| 1 pulg. = .083 pies. | 4 pulg. = .333 pies | 7 pulg = .583 pies. | 10 pulg = .833 pies. |
| 2 — = .167 — | 5 — = .416 — | 8 — = .667 — | 11 — = .917 — |
| 3 — = .25 — | 6 — = .5 — | 9 — = .75 — | 12 — = 1.0 — |

**(4) De otro modo, mídase hacia * cada objeto** 100 ó cualquier número

* Si hay inconveniente en medir hacia los objetos, mídase directamente desde ellos.

de pies y colóquense marcas y mídanse las distancias en pies entre las marcas. Entonces

$$\text{Seno de la mitad del ángulo} = \frac{\text{la mitad de la distancia entre las marcas}}{\text{la distancia medida hacia uno de los objetos.}}$$

Búsquese este seno en la tabla de senos, tangs, etc., págs 106, etc., tómese el ángulo correspondiente y multipliquese por 2.

*N. del T.* — Esta misma tabla es útil empleando el sistema métrico. En efecto: dos reglas de un pie de longitud cada una, dobladas en ángulo, se reemplazan por sus equivalentes de 305 milímetros = 1 pie cada una y para medir las distancias entre sus puntas interiores se sabe que 1 pulg = 25.4 milímetros. Multiplicando, pues, el número de pulgs de la tabla necesarias para obtener un ángulo × 25.4 se tiene el número de milímetros de la abertura. — Ej.: se quiere un ángulo de 75° — 51', la distancia, según la tabla, es 14 pulg — 3/4 = 14.75, lo que × 25.4 será = 374.65 milímetros. Separando las puntas 375 mm se tendrá el ang buscado. Al contrario, si se tiene un ángulo dado y se quiere saber su valor: mídase en mm la distancia entre las puntas, divídase por 25.4 y el cociente será las pulgs que en la tabla darán (enfrente) el ang. — Ej.: dist entre las puntas 375 mm divid por 25.4 = 14.76 ó sean 14 3/4 pulgs. El ángulo que le corresponde en la tabla es = 75° — 51'.

# TRIGONOMETRÍA PLANA

Para las **figuras**, véase la pág. 104*a*.

**1. Medida común de los ángulos.** Si se divide una circunferencia en 360 arcos iguales, cada uno de esos arcos ó el ángulo del centro subtendido por el arco es un **grado** (°). Cada grado está subdividido en 60 **minutos** (′), y cada minuto en 60 **segundos** (″). Un ángulo **recto** es un ángulo de 90°.

**2. Medida circular de los ángulos.** El arco cuya longitud es igual al radio, ó el ángulo del centro subtendido por dicho arco se llama un **radial.** (*N. del T.* abajo.) Como la semicircunferencia (véase adelante capítulo *Círculos*) es = π × radio = π radiales = 180° se tiene :

$$\textbf{1 radial} = \frac{180°}{\pi} = \frac{180°}{3.14159} = 57.2957795...°. \quad \text{Log} = 1.758\ 1226.$$

1 grado = .017 453 292 520 radial.
1 minuto = .000 290 888 209 —
1 segundo = .000 004 848 137 —

**3. Relación entre el arco y el radio.** En cualquier ángulo la longitud del arco con relación al radio se llama *el arco* del ángulo. Ej.: fig. 1 y 3, arco* A = ZB / OZ. Para otras relaciones angulares, véanse §§ 6 y 10.

**4. Angulos positivos y negativos.** — En la fig. 1* supóngase el radio OZ, describiendo, parte ó todo el círculo, en dirección de la flecha, ó sea hacia la izquierda, en sentido **contrario** al movimiento de las agujas de un reloj; los arcos ó ángulos ZB, BC, ZBC, así descriptos, se consideran **positivos.** Los trazados en sentido contrario, de Z hacia E, como ZED, etc., son **negativos.** Ej. : arco ZBCDE = + 280°; arco ZE = — 80°.

**5. Complemento, suplemento, etc.** Para cualquier ángulo **A** se tiene **complemento** de A = 90° — A; **suplemento** de A = 180° — A.

**6. Funciones angulares ó razones angulares.** Líneas trigonométricas son las razones entre los lados de un triángulo rectángulo. Fig. 2. Las razones principales de un ángulo A son : el **seno** (sen A), **coseno** (cos A), **tangente** (tang A), **secante** (sec A), **cosecante** (cosec A) y **cotangente A** (cot A). Para otras razones véanse §§ 3 y 10.

---

* Para las figuras, véase la pág. 104*a*.
(*N. del T.* — Creemos útil introducir esta expresión en español.

En la fig. 2 :*

$$\textbf{Sen}\quad A = \frac{a}{c} = \frac{\text{lado opuesto}}{\text{hipotenusa}}; \qquad \textbf{cosec}\, A = \frac{1}{\text{sen } A} = \frac{c}{a} = \frac{\text{hipotenusa}}{\text{lado opuesto}};$$

$$\textbf{Cos}\quad A = \frac{b}{c} = \frac{\text{lado adyacente}}{\text{hipotenusa}}; \qquad \textbf{sec}\, A = \frac{1}{\cos A} = \frac{c}{b} = \frac{\text{hipotenusa}}{\text{lado adyacente}};$$

$$\textbf{Tang}\ A = \frac{a}{b} = \frac{\text{lado opuesto}}{\text{lado adyacente}}; \qquad \textbf{cot}\, A = \frac{1}{\text{tang } A} = \frac{b}{a} = \frac{\text{lado adyacente}}{\text{lado opuesto}}.$$

**7.** Si se representa el denominador en cada razón (**6**) por una línea de longitud 1, entonces la longitud de la línea que representa el numerador, da el valor de la razón. Ej. : sea en la fig. 3* el radio OB=1; el ángulo ZOU=90°; ZOB un ángulo cualquiera A y sean MB y ZB perpend á OZ. Entonces

$$\textbf{sen}\ \ A = MB; \quad \textbf{cos}\ A = OM = UB; \quad \textbf{tang}\ A = ZB'$$
$$\textbf{cosec}\ A = OB''; \quad \textbf{sec}\ A = OB'; \quad \textbf{cot}\ \ A = UB''$$

El seno, coseno, etc., expresados así, se llaman seno, coseno, etc., **naturales** para el **radio 1.**

$$\cos A = \text{sen } (90° - A) = \text{seno (del complemento de A)}$$
$$\text{cot } A = \text{tang } (90° - A) = \text{tang (del complemento de A)}$$
$$\text{cosec } A = \text{sec } (90° - A) = \text{sec (del complemento de A)}.$$

Véase § 13.

**8. Signos positivos y negativos.** Fig. 4. Supóngase el círculo dividido en 4 cuadrantes, I, II, III y IV empezando de la derecha del diámetro horizontal hacia arriba y á la izquierda en sentido contrario á las agujas de un reloj. Entonces las líneas verticales y horizontales, medidas del diám horizontal hacia arriba y del vertical hacia la derecha, respectivamente son positivas; por el contrario, las líneas medidas de dichos diámetros hacia abajo ó hacia la izquierda son negativas; pero el radio en cualquier cuadrante que esté, siempre que se mida del centro hacia fuera, es positivo.

Así :

Seno (y cosecante) *positivos* en los cuadrantes superiores;
Coseno (y secante) — en el cuadrante de la derecha; ó bien:
Tang (y cotang) — en el I y III cuadrante;

| **En los cuadrantes** | **I** | **II** | **III** | **IV** |
|---|---|---|---|---|
| Incluyendo ángulos de | 0° á 90° | 90° á 180° | 180° á 270° | 270° á 360° |
| Seno y cosecante | + | + | — | — |
| Tang y cotang | + | — | + | — |
| Secante y coseno | + | — | — | + |

* Para las figuras, véase pag. 104*a*.

CENTRAL ARCHAEOLOGICAL LIBRARY New Delhi

**9. Valor numérico de las funciones de ciertos ángulos.**

| | 0° | 30° | 45° | 60° | 90° | 120° | 180° | 270° | 360° |
|---|---|---|---|---|---|---|---|---|---|
| Sen | 0 | $\frac{1}{2}$ | $\frac{1}{2}\sqrt{2}$ | $\frac{1}{2}\sqrt{3}$ | 1 | $\frac{1}{2}\sqrt{3}$ | 0 | $-1$ | 0 |
| Tang | 0 | $\frac{1}{3}\sqrt{3}$ | 1 | $\sqrt{3}$ | $\infty$ | $-\sqrt{3}$ | 0 | $\infty$ | 0 |
| Sec | 1 | $\frac{2}{3}\sqrt{3}$ | $\sqrt{2}$ | 2 | $\infty$ | $-2$ | $-1$ | $\infty$ | 1 |
| Cos | 1 | $\frac{1}{2}\sqrt{3}$ | $\frac{1}{2}\sqrt{2}$ | $\frac{1}{2}$ | 0 | $-\frac{1}{2}$ | $-1$ | 0 | 1 |
| $Sen^2$ | 0 | $\frac{1}{4}$ | $\frac{2}{4}$ | $\frac{3}{4}$ | 1 | $\frac{3}{4}$ | 0 | 1 | 0 |
| $Tang^2$ | 0 | $\frac{1}{3}$ | 1 | 3 | $\infty$ | 3 | 0 | $\infty$ | 0 |
| $Sec^2$ | 1 | $\frac{4}{3}$ | 2 | 4 | $\infty$ | 4 | 1 | $\infty$ | 1 |
| $Cos^2$ | 1 | $\frac{3}{4}$ | $\frac{2}{4}$ | $\frac{1}{4}$ | 0 | $\frac{1}{4}$ | 1 | 0 | 1 |

Para ecuaciones entre funciones angulares, véase 14 á 19.

**10. Otras funciones.** Véase también 3 y 6.

En fig. 3 BN=cuerda 2A= 2 sen A; y **cuerda A**=2 sen (A/2).*

**El seno-verso** MZ, fig. 3, de un áng A=1 — cos A.

Se usa mucho en los trazados de curvas de ferrocarriles.

**El coseno-verso** UU′ = 1 — sen A, fig. 3, de un ángulo A es el seno-verso del complemento BOU de A. Por sus definiciones, seno-verso A (=1 — cos A) y coseno-verso A (=1 — sen A) son siempre positivos. En los 4 cuadrantes, fig. 4, sus valores cambian así:

| Cuadrantes | I | II | III | IV |
|---|---|---|---|---|
| Incluyendo ángulos de | 0° á 90° | 90° á 180° | 180° á 270° | 270° á 360° |
| Seno-verso | 0 á 1 | 1 á 2 | 2 á 1 | 1 á 0 |
| Coseno-verso | 1 á 0 | 0 á 1 | 1 á 2 | 2 á 1 |

**La parte externa de la secante** (exsecante) BB′, fig. 3, de un ángulo A=sec A — 1. Ésta se usa también, como dijimos del seno-verso, en los trazados de curvas para ferrocarriles.

**Tablas de senos, tangs, cotangs, cosenos.**

Para los senos, etc., logarítmicos, véanse las tablas de las funciones logarítmicas trigonométricas ya cerca del final de esta obra.

**11-12. Tabla de líneas naturales.** Las tablas (pág 108-152), contienen los senos, tangentes, cotangs y cosenos naturales de los ángulos de 0° á 90°, de minuto en minuto. Para los ángulos intermedios puede encontrarse el valor de las citadas líneas, con bastante exactitud para casi todos los casos, por una simple proporción. **Para las líneas que no da la tabla,** se tiene:

Secante A=1/cos A; Seno-verso A=1 — cos A;
Cosecante A=1/sen A; Coseno-verso A=1 — sen A;
Cuerda A=2 sen (A/2); Secante externa A=sec A — 1=(1/cos A — 1).

* Para las figs., véase pág. 104*a*.

### Líneas suplementarias y complementarias.

**13.** Siendo A un ángulo cualquiera. Se tiene fig. 5.

$$\begin{aligned}
\text{Sen}\quad A &= \text{sen}\ (180^\circ + A) = \text{sen}\ (180^\circ - A) = \text{sen}\ (A - 180^\circ) \\
&= \cos\ (90^\circ + A) = \cos\ (90^\circ - A) = \cos\ (A - 90^\circ); \\
\text{Cos}\quad A &= \cos\ (180^\circ + A) = \cos\ (180^\circ - A) = \cos\ (A - 180^\circ) \\
&= \text{sen}\ (90^\circ + A) = \text{sen}\ (90^\circ - A) = \text{sen}\ (A - 90^\circ); \\
\text{Tang}\ A &= \text{tang}\ (180^\circ + A) = \text{tang}\ (180^\circ - A) = \text{tang}\ (A - 180^\circ) \\
&= \cot\ (90^\circ + A) = \cot\ (90^\circ - A) = \cot\ (A - 90^\circ).
\end{aligned}$$

### Propiedades de las líneas trigonométricas, figs. 6, 7, 8.

**14. Para cualquier ángulo A** se tiene :

$$\text{Tang}\ A = \frac{\text{sen}\ A}{\cos A}; \qquad \text{sen}^2 A + \cos^2 A = 1;$$

$$1 + \text{tang}^2 A = \sec^2 A; \qquad 1 + \cot^2 A = \text{cosec}^2 A;$$

$$\text{cot}\ A = \frac{1}{\text{tang}\ A} = \frac{\cos A}{\text{sen}\ A}; \quad \text{sec}\ A = \frac{1}{\cos A}; \quad \text{cosec}\ A = \frac{1}{\text{sen}\ A} = \frac{\sec A}{\text{tang}\ A}.$$

De la fig. 4 se deduce sen $(-A) = -\text{sen}\ A$; tang $(-A) = -\text{tang}\ A$; y cos $(-A) = \cos A$.

**15. Para dos ángulos cualesquiera A y B** podría demostrarse que :

$$\text{sen}\ (A+B) = \text{sen}\ A.\cos B + \cos A.\text{sen}\ B;$$
$$\text{y... cos}\ (A+B) = \cos A.\cos B - \text{sen}\ A.\text{sen}\ B;$$

de donde dividiendo miembro á miembro las dos ecuaciones y después dividiendo el numerador y denominador del segundo miembro por cos A cos B, se obtendrá, haciendo las debidas sustituciones :

$$\text{tang}\ (A + B) = \frac{\text{sen}\ (A + B)}{\cos\ (A + B)} = \frac{\text{tang}\ A + \text{tang}\ B}{1 - \text{tang}\ A\ \text{tang}\ B}.$$

**16.** Haciendo A=B en las fórmulas últimas para (A+B) se tiene :

$$\text{sen}\ 2A = 2\ \text{sen}\ A.\cos A$$
$$\cos 2A = \cos^2 A - \text{sen}^2 A = 1 - 2\ \text{sen}^2 A = 2\cos^2 A - 1;$$

$$\text{tang}\ 2A = \frac{2\ \text{tang}\ A}{1 - \text{tang}^2 A}.$$

y poniendo en lugar de B, —B, se tiene; véase final 14.

$$\text{sen}\ (A - B) = \text{sen}\ A\cos B - \cos A\ \text{sen}\ B;$$
$$\cos (A - B) = \cos A\cos B + \text{sen}\ A\ \text{sen}\ B;$$

$$\text{tang}\ (A - B) = \frac{\text{tang}\ A - \text{tang}\ B}{1 + \text{tang}\ A.\ \text{tang}\ B}.$$

**17.** Como $\cos 2A = 1 - 2\,\text{sen}^2 A$; se tiene poniendo $A/2$ por A; $\cos A = 1 - 2\,\text{sen}^2 A/2$; de donde $\text{sen}\ \frac{A}{2} = \sqrt{\frac{1 - \cos A}{2}}$ y como $\cos 2A = 2\cos^2 A - 1$; se tiene $2\cos^2 \frac{A}{2} = \cos A + 1$; de donde $\cos \frac{A}{2} = \sqrt{\frac{1 + \cos A}{2}}$ y como $\text{tang}\ \frac{A}{2} = \frac{\text{sen}\ A/2}{\cos A/2} = \sqrt{\frac{1 - \cos A}{1 + \cos A}} = \frac{1 - \cos A}{\text{sen}\ A} = \frac{\text{sen}\ A}{1 + \cos A}$.

**18. Fórmulas que transforman una suma ó diferencia en producto:**

$$\text{sen}\ A + \text{sen}\ B = 2\ \text{sen}\ \frac{A + B}{2}.\ \cos \frac{A - B}{2}.$$

$$\text{sen}\ A - \text{sen}\ B = 2\ \text{sen}\ \frac{A - B}{2}.\ \cos \frac{A + B}{2}.$$

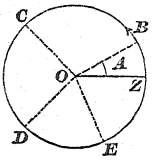

Fig. 1.

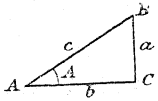

Fig. 2.

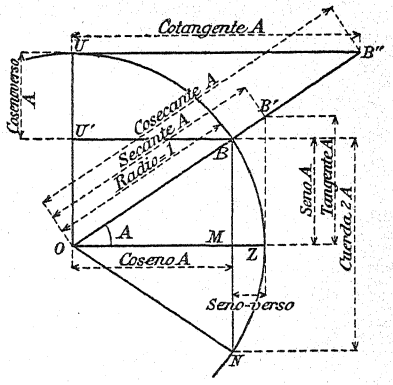

Fig. 3.

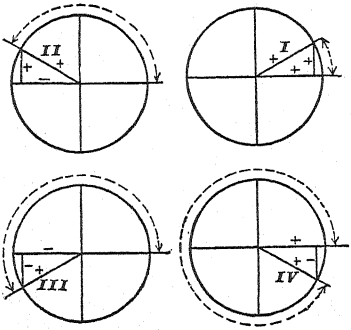

Fig. 4.

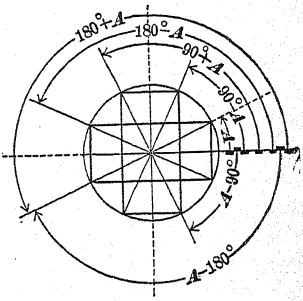

Fig. 5.

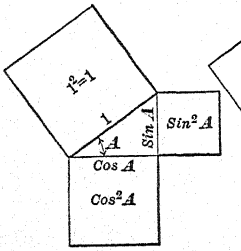

Fig. 6

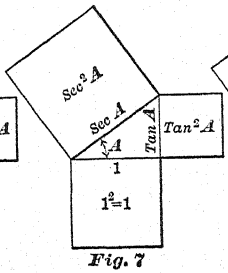

Fig. 7

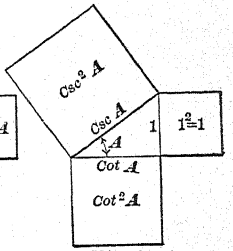

Fig. 8

(*Obs. del T.* — *Sin* en inglés equivale á *seno* en español.)

$$\cos A + \cos B = 2 \cos \frac{A+B}{2} . \cos \frac{A-B}{2} .$$

$$\cos A - \cos B = -2 \operatorname{sen} \frac{A+B}{2} . \operatorname{sen} \frac{A+B}{2} .$$

Véase también (20) para las fórmulas usadas en la resolución de los triángulos.

**19.** Cualquier línea trigonométrica en función de otra, figs. 6, 7 y 8.

En función del seno :

$$\cos^2 A = 1 - \operatorname{sen}^2 A ; \cos A = \sqrt{1 - \operatorname{sen}^2 A} :$$

$$\operatorname{tang} A = \frac{\operatorname{sen} A}{\cos A} = \frac{\operatorname{sen} A}{\sqrt{1 - \operatorname{sen}^2 A}}$$

$$\sec A = \frac{1}{\cos A} = \frac{1}{\sqrt{1 - \operatorname{sen}^2 A}}$$

En función de la tangente :

$$\sec^2 A = 1 + \operatorname{tang}^2 A ; \sec = \sqrt{1 + \operatorname{tang}^2 A};$$

$$\cos A = \frac{1}{\sec A} = \frac{1}{\sqrt{1 + \operatorname{tang}^2 A}}$$

$$\operatorname{sen} A = \frac{\operatorname{tang} A}{\sec A} = \frac{\operatorname{tang} A}{\sqrt{1 + \operatorname{tang}^2 A}}$$

**20. Fórmulas usadas en la resolución de los triángulos.** Fig. 9.

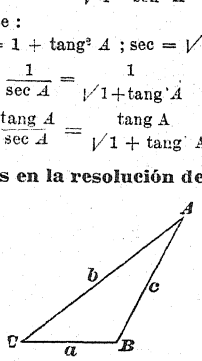

**Fig. 9.**

$$\frac{\operatorname{sen} A}{\operatorname{sen} B} = \frac{a}{b}; \; a^2 = b^2 + c^2 - 2bc \cos A;$$

$$\operatorname{tang} \frac{A-B}{2} = \frac{a-b}{a+b} . \operatorname{tang} \frac{A+B}{2} ;$$

$$\operatorname{tang} \frac{A}{2} = \frac{r}{s-a} ; \text{ aquí } s = \frac{a+b+c}{2} \text{ y } r = \sqrt{\frac{(s-a)(s-b)(s-c)}{s}}$$

$= $ al radio del círculo inscripto.

$$\text{Área del triángulo} = \frac{ab \operatorname{sen} C}{2} = rs = \sqrt{s(s-a)(s-b)(s-c)}$$

$$= \frac{\operatorname{sen} A \operatorname{sen} C b^2}{2 \operatorname{sen} B} .$$

(Véanse también los capítulos Triángulos y Trigonometría Plana.)

# LOGARITMOS DE LAS FUNCIONES TRIGONOMÉTRICAS

(1) **El logaritmo del seno, tang, etc.** (log sen, log tan, etc.), de un arco es el *logaritmo* del seno, tang, etc., *natural* de dicho arco. Así:

sen nat 37°= .60182; y
log sen 37°=log .60182 =1.779 463
= .779 463 — 1
=9.779 463 — 10.

En las tablas, con el objeto de evitar las cantidades negativas, se emplea la *tercera* forma (log sen 37°=9.779 463 — 10); pero el « — 10 » se sobrentiende que está omitido.

Damos **dos tablas** de los logs de las funciones trigonométricas, es decir: una

« **tabla principal** », págs. 151*j* á 152*x*
y una
« **tabla especial** », págs. 151*c* á 151*i*.

La **principal** da dichos valores para cada **minuto** del cuadrante de 0° á 90°.

La **especial**, los da á **pequeños intervalos**, para ángulos pequeños y grandes (de 0° á 2° y de 88° á 90°), en los cuales ciertas funciones cambian tan rápidamente, que á los intervalos de un minuto entre los arcos corresponden valores de las funciones demasiado amplios para interpolaciones satisfactorias. Véanse §§ 7 á 9.

## Tabla principal.

(2) **Esta tabla**, págs. 151*j* á 152*x* da con 6 decimales el

**log sen, log cos, log tan y log cot** *

del arco de minuto en minuto ó sea de 0°0′ á 89°60′ (90°). Véase también (6) más abajo.

(3) Para arcos de 0° á 45°; **léase hacia abajo**, como en la columna izquierda de los minutos, usando los títulos que están á la cabeza de las columnas. Para arcos de 45° á 90°, **léase hacia arriba**, como en la columna de la derecha, usando los títulos que están al pie de las columnas.

(4) **Ejemplo.** Encontrar el log del sen 7°34′. En la cabeza de la pág. 151*o*, á la izquierda, en tipo grueso, se encuentra 7°; y debajo de él, en la primera columna ó columna de los minutos (leyendo *hacia abajo*), encontramos 34; opuesto á éste en la próxima ó segunda col, *bajo* « Seno », encontramos 9.119 519, el log buscado de 7°34′.

(5) **Ejemplo.** Encontrar el log cos 82°26′. Al pie de la pág. 151*o*, á la derecha, en tipo grueso, encontramos 82°; y sobre éstos, en la col de la derecha ó col de los minutos (leyendo hacia arriba), encontramos 26; opuesto al cual, en la segunda columna de izquierda á derecha **sobre** « Coseno », encontramos 9.119 519, que es el log cos 82°26′ buscado.

(6) **Para arcos entre 90° y 180°**, tenemos las relaciones siguientes:

sen $a$ = sen (180 — $a$); cos $a$ = 0 — cos (180° — $a$);
tan $a$ = 0 — tan (180° — $a$); cot $a$ = 0 — cot (180° — $a$).

---

* **Secante** $a = \frac{1}{\cos a}$; log sec $a$ = 0 — log cos $a$. **Cosecante** $a = \frac{1}{\text{sen } a}$; log cosec = 0 — log sen $a$.

Por tanto, log sen, log cos, log tan y log cot de un ángulo $a$, entre 90° y 180°, son numéricamente iguales respectivamente á los log sen, log cos, log tan, log cot, **del suplemento** $180° - a$. En la tabla principal, estas funciones se encuentran directamente usando los encabezamientos en tipo grueso, en los ángulos de la parte baja de la izquierda y alta de la derecha; notando que, la columna de los minutos, á la *izquierda*, pertenece á los grados de la izquierda (ya estén á la cabeza ó pie de la columna, así como la columna de los minutos á la derecha pertenece á los grados de la derecha.

Así: log sen 172°26′ = 9.119 519;
log (0 — cos 172°26′) = 9.996 202.

(7) **Para arcos intermedios de los dados en la tabla principal** (págs. 151*j* á 152*x*), si el arco no está entre 0° y 2° ó entre 88° y 90°, ó entre 178° y 180° (véanse §§ 8 y 9), **interpólese** por medio de la columna encabezada D. 1″ (que significa, diferencia de las funciones para 1 segundo en los ángulos) como en el ejemplo siguiente:

| Dado. | Se busca. | La tabla da D. 1″ = 15.87 y 9.118 567 = | Resultado. |
|---|---|---|---|
| $a$ = 7°33′12″ | log sen $a$ | log sen 7°33′0″ | 9.118 567 + 12 D. 1″ = 9.118 757; |
| $a$ = 82°26′48″ | log cos $a$ | log cos 82°27′0″ | 9.118 567 + 12 D. 1″ = 9.118 757; |
| log sen $a$ = 9.118 757 | $a$ | log sen 7°33′0″ | 7°33′0″ + 190 * D.1″ = 7°33′12″; |
| log cos $a$ = 9.118 757 | $a$ | log cos 82°27′0″ | 82°27′0″ — 190 * D.1″ = 82°26′48″. |

**Tabla especial, págs. 151*c* á 151*i*.**

(8) Para el log sen, tan, cot, de los arcos de 0°0′ á 1°60′ (= 2°0′); y para los log cos, cot, tan, de arcos de 88°0′ á 89°60′ (= 90°0′); la diferencia entre los sucesivos logaritmos varía tan rápidamente, que el uso de la columna D. 1″, con intervalos de 1 minuto entre arcos tabulares, daría resultados de insuficiente exactitud.

(9) Para estos casos damos la **tabla especial de 5 decimales**, págs. 1083 á 1090, con más pequeños intervalos entre los arcos, así:

| para arcos de | intervalo | páginas. |
|---|---|---|
| 0°00′ á 0°18′ | 1 segundo | 1083 — 5 |
| 0°18′ á 0°30′ | 3 segundos | 1086 — 7 |
| 0°30′ á 0°40′ | 5 — | 1088 |
| 0°40′ á 0°60′ | 10 — | 1089 |
| 1° 0′ á 1°60′ | 30 — | 1090 |

(10) **Tangentes de ángulos próximos á 90°, y cotangentes de ángulos próximos á 0°**, no se dan en la tabla especial, pero tenemos:

$$\log \tan a = 0 - \log \cot a; \qquad \log \cot a = 0 - \log \tan a.$$

(11) Con funciones de sólo cinco decimales, tenemos:

en arcos de 0° á 0°18′; log sen $a$ = log tan $a$ = 0 — log cot $a$;
— 89°42′ á 90°; log cos $a$ = log cot $a$ = 0 — log tan $a$.

(12) Para arcos de 0°0′ á 0°18′ (á un segundo de intervalo), por supuesto que no se necesita de interpolación, para segundos completos. Para los otros ángulos arriba mencionados, el mayor **error debido á la interpolación** es menor que 1 en la quinta decimal. En la tabla principal, log sen 2° 0′ 30″, el **error debido á la interpolación**, es como .4 de la quinta cifra.

**Ejemplos** de interpolación usando la tabla especial.

La tabla da

Dado, $a$ = 1°48′10″ } log sen 1°48′30″ = 8.49 908
Se pide, log sen $a$ } log sen 1°48′ 0″ = 8.49 708
dif 0° 0′30″ 0.00 200

$$\text{Resultado} = \log \text{ sen } a = 8.49\ 708 + \frac{10}{30} \times 200 = 8.49\ 775$$

* 9.118 757 — 9.118 567 = .000 190.

| | | La tabla de |
|---|---|---|
| Dado, log sen $a$ = 8.49775 | 8.49 908 | = log sen 1°48'30" |
| Se pide, $a$ | 8.49 708 | = log sen 1°48' 0" |
| | dif 0.00 200 | 0° 0'30" |

$$\text{Resultado} = a = 1°48'0'' + \frac{67^*}{200} \times 30'' = 1°48'10''$$

---

* 67 = 8.49 775 — 8.49 708.

(*N. del T.* — En las tablas que siguen en encuentra *sine* en inglés por *seno* y *cosine* por *coseno*, etc.; pero como se comprende tan facilmente las lineas á que se refieren, hemos pasado sobre eso para aprovechar en esta parte los mismos clisés del autor inglés.)

| Log sine = Log tangent = 0 − Log cotangent. | | | | | | | |

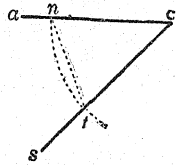
**La tabla de las cuerdas** que sigue nos permite trazar ángulos sobre el papel más exactamente que con un transportador ordinario. Para hacer esto, después de haber trazado y medido el primer lado (digamos *ac*) de la figura que será delineada; desde su extremo *c* como centro se describe un arco de círculo *n* y de suficiente longitud. El radio *cn* del arco, debe ser lo más grande posible y se debe suponer igual á la unidad. Divídaselo y subdivídaselo decimalmente para usarlo como escala para representar las cuerdas que se tomen de la tabla, en la cual las longitudes de éstas están dadas en partes de dicho radio 1. Habiendo descripto el arco,



búsquese en la tabla la longitud de la cuerda *nt* que corresponde al ángulo *nct*. Supongamos que este ángulo sea de 45° y encontramos entonces que la cuerda de la tabla es .7654 de nuestro radio 1. Por tanto, desde *n* trazamos la cuerda *nt* igual á .7654 del radio elegido y la línea *cs* tirada por el punto *t* formará el ángulo requerido *act* de 45°. Así para cada ángulo. El grado de exactitud que se obtenga dependerá evidentemente de la longitud del radio y de la precisión de los instrumentos. Este método se hace preferible al del transportador á proporción que la longitud de los lados de los ángulos exceda el radio del transportador. Con un trasportador de 10 á 15 centímetros de radio, y si los lados de los ángulos no exceden en mucho á los mismos límites del transportador, será generalmente preferible éste. Los compases de división de las cajas de instrumentos son rara vez adecuados para trazar arcos exactos de más de 15 cm de diámetro. En la práctica no es necesario describir efectivamente todo el arco sino simplemente la parte próxima á *t*. Así evitamos el frecuente uso de la goma y también gastarle la punta al lápiz. Para radios mayores podemos prescindir del compás y usar una tira de papel estrecha con la longitud del radio marcada en una orilla, colocándola de *c* hacia *s* y colocando al mismo tiempo otra tira (con una orilla dividida en partes del radio) de *n* hacia *t*, podemos por tanteo encontrar el punto exacto de intersección en *t*. En semejantes casos la práctica y un poco de ingenio son muy esenciales para obtener resultados satisfactorios. No podemos dedicar mayor espacio á este asunto.

# CUERDAS PARA UN RADIO 1

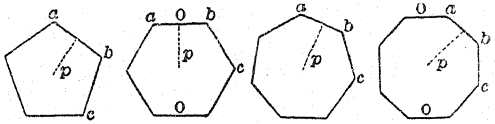
## POLÍGONOS



**Pentágono.** 5 *lados.* **Exágono.** 6 *lados.* **Heptágono.** 7 *lados.* **Octógono.** 8 *lados.*

Polígono es toda figura plana terminada por líneas rectas. Si todos los lados y ángulos son iguales es un polígono **regular;** si no, es **irregular.** Por supuesto, el número de los polígonos es infinito.

**Tabla de polígonos regulares.**

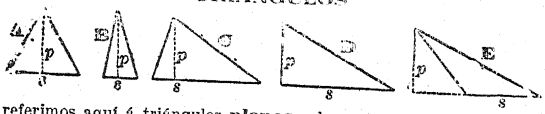
| Número de lados. | Nombre del polígono. | **Área** = (cuadrado de un lado) multiplicado por | **Radio** del círculo circunscrito = lado multiplicado por | **Ángulo** interior *abc*. | **Ángulo** del centro *apb*. |
|---|---|---|---|---|---|
| 3 | Triángulo equilátero. | 0.433013 | 0.577350 | 60° | 120° |
| 4 | Cuadrado. | 1.000000 | 0.707107 | 90° | 90° |
| 5 | Pentágono. | 1.720477 | 0.850651 | 108° | 72° |
| 6 | Exágono. | 2.598076 | 1.000000 | 120° | 60° |
| 7 | Eptágono. | 3.633912 | 1.152382 | 128° 34.2857 | 51° 25.7143 |
| 8 | Octógono. | 4.828427 | 1.306563 | 135° | 45° |
| 9 | Nonágono. | 6.181824 | 1.461902 | 140° | 40° |
| 10 | Decágono. | 7.694209 | 1.618034 | 144° | 36° |
| 11 | Endecágono. | 9.365640 | 1.774733 | 147° 16.3636 | 32° 43.6364 |
| 12 | Dodecágono. | 11.196152 | 1.931854 | 150° | 30° |

**Área de cualquier polígono regular** = longitud de lado *ab* × perpendicular *p* trazada del centro de la figura al centro del lado × la mitad del número de los lados.

**La suma de los ángulos interiores** *abc*, etc., de cualquier polígono regular ó irregular es = 180° × (número de lados—2).

**El ángulo del centro subtendido por un lado en cualquier polígono regular** = 360 ÷ número de lados.

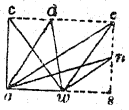
TRIÁNGULOS



Nos referimos aquí á triángulos **planos** solamente, es decir, á aquellos cuyos lados son **rectos.**

**Un triángulo es equilátero** cuando sus lados son iguales, como A; **isósceles**, cuando sólo dos lados son iguales, B; **escaleno**, cuando sus lados son desiguales como C, D y E; **acutángulo**, cuando todos sus ángulos son agudos, es decir, menores de 90°, como A, B y C; **rectángulo**, cuando contiene un ángulo recto, D; **obtusángulo**, cuando contiene un ángulo obtuso, es decir, mayor de 90°, como E.

**La suma de los tres ángulos de cualquier triángulo es igual á dos ángulos rectos** ó 180°; por tanto, si conocemos dos de ellos podemos encontrar el tercero restando la suma de ellos de 180°. **Todos los triángulos que tienen iguales bases** é iguales alturas tienen también iguales áreas, así



las áreas de *awc*, *awd*, *awe*, son iguales entre sí. **El área de cualquier triángulo** es igual á la mitad de la de cualquier paralelogramo que tenga la misma base y altura. **Las áreas de triángulos que tienen iguales bases** pero diferentes alturas, están entre sí en proporción á sus alturas. Así el triángulo *awn*, con una altura *sn* mitad de *se*, es la mitad de cualquiera de los otros tres triángulos que tienen la misma base *aw* pero doble altura *se*.

**El área de un triángulo cualquiera** como los de las figuras A, B, C, D, F = la mitad de la base *s* × la altura ó distancia *p* del vértice opuesto á la base. Cualquier lado puede tomarse como la base de un triángulo; pero la altura debe

medirse siempre desde el vértice opuesto bajando una perpendicular al lado elegido como base, para lo cual algunas veces debe prolongarse la base como en la figura E, pero la prolongación no debe considerarse como parte de la base.

El área de cualquier triángulo equilátero = .433013 × cuadrado de un lado.

**Encontrar el área de un triángulo conociendo los tres lados.** Súmense juntos; divídase la suma por 2; de esta mitad réstese cada lado separadamente; multipliquese entre sí la mitad de la suma y los tres residuos así hallados y tómese del producto total la raíz cuadrada.

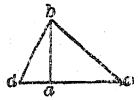
**Ej.** : Sean los tres lados = 20, 30, 40, pies ó metros, $20+30+40 = 90$ y $\frac{90}{2} = 45$ y $45-20 = 25$; $45-30 = 15$ y $45-40 = 5$ y $45\times25\times15\times5 = 84{,}375$ y la raíz cuadrada de 84,375 es 290.47 pies ó metros cuadrados es el área requerida.

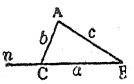
**Para encontrar el área teniendo un lado y los dos ángulos adyacentes.** Súmense los dos ángulos, réstese la suma de 180°, la diferencia será el ángulo opuesto al lado dado; búsquese el seno de este ángulo así como también los senos de los otros ángulos y multipliquense entre sí estos dos últimos. Entonces, lo que el seno del ángulo sencillo es al producto de los senos de los otros dos ángulos será el *cuadrado* del lado dado al *doble* del área requerida.

**Para encontrar el área, teniendo dos lados y el ángulo comprendido.** Multipliquense entre sí los dos lados y el seno del ángulo comprendido y divídase por dos el producto.

**Ej.** : Lados 650 y 980 pies ó metros, ángulo comprendido 69° 20′. Por la tabla encontramos que el seno de 69° 20′ es .9356, por tanto $\frac{650\times980\times.9356}{2} = 297988.6$ pies ó metros cuadrados (según la medida elegida) es el área del triángulo.

**Para encontrar el área teniendo los tres ángulos y la altura** *ab*. Búsquense los senos de los tres ángulos, multipliquense entre sí los senos de los ángulos *d* y *o*; divídase por este producto el seno del ángulo *b*, multipliquese el cociente por el cuadrado de la altura *ab* y divídase por 2.





**Para encontrar cualquier lado, como** *do*, **teniendo los tres ángulos** *d*, *b*, *o*, **y el área** : (sen *d* × sen *o*) : sen *b* : : el doble del área : cuadrado de *do*.

**La altura de un triángulo equilátero** es igual á un lado × .866025. Por consiguiente, uno de sus lados es igual á la altura dividida por .866025, ó la altura × 1.1547.

**También para encontrar un lado** se multiplica la raíz cuadrada de su área por 1.51967. El lado de un triángulo equilátero multiplicado por .658037 = al lado de un cuadrado de la misma área; ó multiplicado por .742517 da el diámetro de un círculo de igual área.

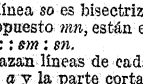
Las siguientes reglas se aplican á cualquier triángulo plano :

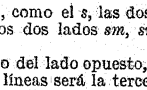
**1.** Los tres ángulos sumados dan 180°; ó dos ángulos rectos.

**2.** Cualquier ángulo exterior como A*Cn* es igual á los dos internos opuestos A, B.

**3.** El mayor lado está opuesto al ángulo mayor.

**4.** Los lados están entre sí como los senos de los ángulos opuestos. Así el lado *a* es al lado *b* como el seno de A es al seno de B.





**5.** Si una línea *so* es bisectriz de cualquier ángulo, como el *s*, las dos partes *mo*, *on* del lado opuesto *mn*, están entre sí como los otros dos lados *sm*, *sn*; es decir, que *mo* : *on* : : *sm* : *sn*.

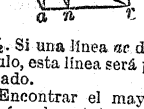
**6.** Si se trazan líneas de cada ángulo *rst* al centro del lado opuesto, se cruzarán en un punto *a* y la parte corta de cada una de las líneas será la tercera parte de la línea total. También *a* **será el centro de gravedad** del triángulo.

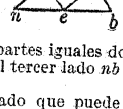
**7.** Si se trazan líneas bisectrices de los tres ángulos, se encontrarán en un punto equidistante de cada lado y, por consiguiente, ese punto será **centro del círculo** máximo que puede trazarse en ese triángulo.

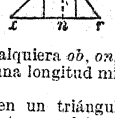
**8.** Si se traza una línea *sn* paralela á cualquier lado *ca*, los dos triángulos *rsn*, *rca* serán semejantes.

**9.** Para dividir cualquier triángulo *acr*, en dos partes iguales con una línea *sn* paralela á cualquiera de sus lados, *ca* se procederá así: sobre cualquiera de los otros lados, *ar*, como diámetro, descríbase una semicircunferencia *aor* y búsquese su punto medio *o*. De *r* (opuesto á *ca*), con un radio *ro*, descríbase el arco *on*. De *n* trácese *ns* paralela á *ca*.

**10.** Para encontrar el mayor paralelogramo que puede trazarse en cualquier triángulo dado, *onb*. Córtense en la mitad los tres lados en *a*, *c*, *e*, y unánse *ac*, *ae*, *ec*. Entonces cualquiera de los paralelogramos *aebc*, *aeco*, *accn*, cada uno igual á la mitad del triángulo, será el paralelogramo que se requiere. Cualquiera de estos paralelogramos puede convertirse fácilmente en un rectángulo de igual área que también será el mayor que pueda ser trazado en el triángulo.







**10½.** Si una línea *nc* divide en partes iguales dos lados cualquiera *ob*, *on*, de un triángulo, esta línea será paralela al tercer lado *nb* y tendrá una longitud mitad de dicho lado.

**11.** Encontrar el mayor cuadrado que puede trazarse en un triángulo *axr*. De un ángulo *a* trácese una perpendicular *an* al lado opuesto *xr* y búsquese su longitud. Entonces *on* ó un lado *vt* del cuadrado será $= \frac{xr \times an}{xr + an}$.

**Advertancia.** Si el triángulo es tal que se pueden trazar dos ó tres perpendiculare análogas, pueden encontrarse entonces dos ó tres cuadrados iguales.

## Triángulos rectángulos.

Todo lo anterior se aplica también á los triángulos rectángulos, pero lo que sigue se aplica solamente á ellos.

Llamemos al ángulo recto A y á los otros B, C. Llamemos los lados respectivamente opuestos á los ángulos A, B. C; *a*, *b*, *c*. Entonces tendremos

$$a = \frac{c}{\text{sen C}} = c \times \sec B = \frac{b}{\cos C} = b \times \sec C = \sqrt{b2 + c2}$$

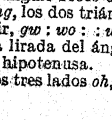
$b = a \times \text{sen B} = a \times \cos C = c \times \cot C = c \times \text{tang B}.$

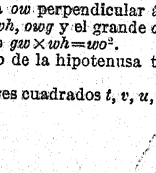
$c = a \times \text{sen C} = a \times \cos B = b \times \text{tang C}.$

También $\text{sen C} = \frac{c}{a}$; $\cos C = \frac{b}{a}$; $\text{tang C} = \frac{c}{b}$;

y $\text{sen B} = \frac{b}{a}$; $\cos B = \frac{c}{a}$; $\text{tang B} = \frac{b}{c}$.

Sen A ó 90° = 1; cos A = 0; tang A = el infinito; sec A = infinito.





**1.** Si por el ángulo recto *o* se traza una línea *ow* perpendicular á la hipotenusa ó lado mayor *hg*, los dos triángulos pequeños, *owh*, *owg* y el grande *ohg* serán semejantes; es decir, $gw : wo :: wo : wh$; y por tanto $gw \times wh = wo^2$.

**2.** Una línea lirada del ángulo recto al centro de la hipotenusa tendrá de largo la mitad de la hipotenusa.

**3.** Si sobre los tres lados *oh*, *og*, *gh*, trazamos tres cuadrados *t*, *v*, *u*, ó tres círculos,

ó tres triángulos ó cualesquiera otras tres figuras que sean semejantes : el área de la más grande es igual á la suma de las áreas de las otras dos.

**4.** En un triángulo cuyos lados estén como 3, 4, y 5 (como son los del triángulo A, B, C) los ángulos son muy aproximadamente 90°; 53° 7′ 48″, 38 y 36° 52′ 11 62″. Sus senos 1, 8 y 6. Sus tangentes, el infinito; 1.3333 y 0.75.

**5.** Uno cuyos lados estén como 7, 7, y 9, tiene muy aproximadamente un ángulo de 90° y dos de 45° cada uno. Estas cantidades son suficientemente aproximadas para casi todos los casos prácticos.

# TRIGONOMETRÍA PLANA

La trigonometría plana enseña á encontrar elementos desconocidos de los triángulos planos por medio de otros conocidos permitiéndonos por este medio medir distancias inaccesibles, etc. Un triángulo tiene seis elementos, á saber : tres lados y tres ángulos, y si conocemos 3 cualesquiera de sus elementos, con tal que entre un lado por lo menos en los 3 conocidos, podemos encontrar los otros tres. Los cuatro casos siguientes abrazan todo el asunto y deben los estudiantes aprenderlos de memoria.

**1er Caso. Teniendo dos ángulos y un lado encontrar los otros dos lados y el otro ángulo.**

Súmense los dos ángulos y réstese la suma de 180, la diferencia será el tercer ángulo, y para los lados procédase así :

Seno del ángulo opuesto al lado dado : Seno del ángulo opuesto al lado que se busca = El lado dado : Lado que se busca.

Úsese ahora, para encontrar el otro lado que falta, al lado que se ha encontrado como el lado dado y de la misma manera búsquese el tercer lado.

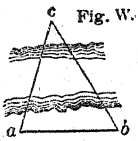


Fig. W.

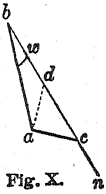

Fig. X.

**2.° Caso. Teniendo dos lados** *ba, ac,* **fig. X, y el ángulo** *abc* **opuesto á uno de ellos,** encontrar el otro lado y los otros ángulos.

El lado *ac* opuesto al ángulo dado *abc* : El otro lado dado *ba* = Seno del ángulo dado *abc* : Seno del ángulo *bda*, ó *bca* opuesto al otro lado dado *ba*.

Habiendo encontrado el seno tómese el ángulo correspondiente en la tabla de los senos naturales; pero al hacer esto, si el lado *ac* opuesto al ángulo es más pequeño que el otro lado dado *ba,* recuérdese que un ángulo y su suplemento tienen el mismo seno. Así en la fig. X el seno según se encontró de la tabla pertenece tanto al ángulo *bca* como al *bda* que es suplemento de *acb* si se hace *ad* igual *ac* formando un triángulo isóseles *dac*. Hasta que no se determine el otro lado *bc* no se sabe si el triángulo resuelto es el *adb* ó el *acb*. No sucede así si *ac* es tan grande ó mayor que *ba,* pues entonces no puede haber duda, porque en ese caso no puede trazarse el lado *ac* hacia *b* como en *ad* sino sólo hacia *n* y el ángulo *bca* será el único á que corresponde el seno hallado en la tabla.

Cuando se conozcan los dos ángulos *abc, bca,* búsquese el lado que falta como en el caso 1.°

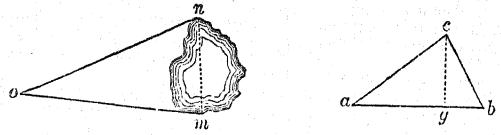
Para encontrar el ángulo que falta *bac* súmense el ángulo *abc* que se dió primero y el *bca* encontrado como se dijo arriba y réstese su suma de 180°.

**3.er Caso. Teniendo dos lados y el ángulo comprendido entre ellos.** Réstese el ángulo conocido de 180°, la diferencia será la suma de los dos ángulos desconocidos; divídase esta suma por 2 y búsquese la tangente del cociente. Entonces

La suma de los dos lados dados : á su diferencia = Tangente de la semisuma de los dos ángulos desconocidos : Tangente de la semidiferencia de estos mismos ángulos.

Despéjese el cuarto término y tómese en la tabla de las tangentes el ángulo opuesto á esta última tangente, agréguese este ángulo á la mitad de la suma de los dos ángulos desconocidos y dará el ángulo opuesto al lado dado más largo; y para el ángulo opuesto al lado dado más corto, réstese aquel de la misma mitad de la suma de los dos ángulos. Habiendo encontrado así los ángulos, búsquese el tercer lado, aplicando el 1.er caso.

Como un ejemplo práctico del uso del caso 3.° podemos determinar la distancia, *nm*, en un estanque ó lago, etc., midiendo dos líneas *mo*, *no*, y el ángulo *nom*. Con este dato podemos calcular *nm*; también trazando los dos lados y el ángulo sobre el papel por medio de una escala podemos medir después *nm* sobre el dibujo en partes de la escala.



**4.° Caso. Conociendo los tres lados** encontrar los tres ángulos.

En un lado *ab*, como base, trácese (ó supóngase trazada) una perpendicular *cg* bajada del ángulo opuesto *c*; búsquese la diferencia entre los otros dos lados *ac* *cb*, y también la suma de ellos; y dígase :

La base : La suma de los otros dos lados = La diferencia de los otros dos lados : La diferencia de las dos partes *ag*, *bg* de la base

Súmese la mitad de esta diferencia de las partes con la mitad de la base *ab*; la suma será la parte más larga *ag*, la que restada de la base total *ab* da la parte más corta *gb*. Por estos medios obtenemos en cada uno de los pequeños triángulos *acg*, *cgb*, dos lados (á saber : *ac*, *ag*; *cb*, *gb*), y un ángulo (el ángulo recto *cga*, ó *cgb*) opuesto á uno de los lados dados. Luego empléese el método del 2.° caso para buscar los ángulos *a*, *b*. Hecho esto réstese de 180° la suma de ellos y se tendrá el ángulo *acb*.

**2.° Modo.** Llámese **la mitad** de la suma de los tres lados *s*; y llámense los dos lados que forman cualquiera de los dos ángulos, *m*, *n*; entonces el seno de la mitad de ese ángulo será igual á $\sqrt{\frac{(s-m)\times(s-n)}{m\times n}}$.

**Ej. 1.° Encontrar la distancia, de *a*, á un objeto inaccesible *c*.**

Mídase una línea *ab* y desde sus extremos mídanse los ángulos *cab*, *cba*. Habiendo encontrado así un lado y dos ángulos del triángulo *abc*, calcúlese *ac* por el caso 1.°

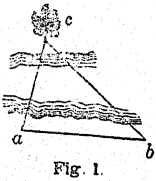


Fig. 1.

Si no se necesita gran exactitud trácese la línea *ab* sobre el papel en una escala conveniente y por medio de un transportador colóquense los ángulos *cab*, *cba*: trácense *ac*, *cb* y mídase entonces en el papel *ac*, en la misma escala.

**Ej. 2.° Encontrar la altura de un objeto vertical** *na.*
Colóquese el instrumento de medir ángulos en un punto conveniente *o;* mídase a distancia *oa;* ó si *oa* no puede medirse á consecuencia de algún obstáculo,

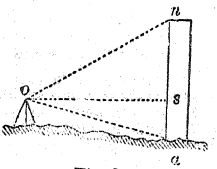

Fig. 2.

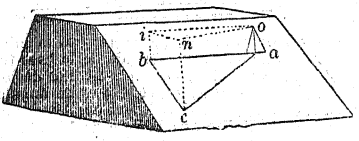
calcúlese por medio del mismo procedimiento que *ac* en la figura 1. Entonces, dirigiendo primero horizontalmente el instrumento *, como en *s*, mídase el ángulo de depresión *son*, supongámoslo de 12°, también el ángulo *son* supongámoslo de 30°. Estos dos ángulos unidos dan el ángulo *aon*=42°. Ahora, en el triángulo pequeño *osa*, teníamos el ángulo *osa* igual á 90° porque *an* es vertical y *os* horizontal, y como los tres ángulos de cualquier triángulo son iguales á 180°, si restamos los ángulos *osa* (90°) y *soa* (12°) de 180° la diferencia (78°) será el ángulo *oas*, ó *oan*. Por tanto en el triángulo *ona* tenemos un lado *oa* y dos ángulos *aon*, *oan* para calcular el lado *an* según el caso 1.°

---

* **Los ángulos y las distancias, en un terreno inclinado, deben ser medidos horizontalmente.** El círculo horizontal graduado de un instrumento mide evidentemente el ángulo entre dos objetos horizontales ó el de sus proyecciones en un plano horizontal, no importa lo más alto que esté el uno respecto al otro. Algunas veces es necesario dirigir un anteojo del instrumento hacia arriba y el otro hacia abajo. Por consiguiente los lados de los triángulos que descansan sobre terrenos inclinados deben medirse también horizontalmente porque de lo contrario no puede haber la relación que se busca entre ellos. Así, en el triángulo *abc* situado sobre un terreno inclinado,



el instrumento en *o*, mide el ángulo horizontal *ion*, y no el ángulo *bac*. Por tanto el lado que le corresponde á este ángulo horizontal *ion* es la distancia horizontal *in* y no la distancia inclinada *bc*. En otras palabras, cuando los lados y ángulos de un triángulo están en terreno inclinado no buscamos sus medidas reales sino las horizontales de sus proyecciones. Esta advertencia corresponde á todas las medidas de granjas, ferrocarriles, triangulaciones de campos, etc., etc.; y la falta de una estricta atención en este punto es una causa de errores casi inevitables (afortunadamente de insignificantes consecuencias en la práctica) que ocurren en casi todas las operaciones ordinarias sobre el terreno.

**Cuando se usa un sextante**, los ángulos entre objetos á diferentes alturas, como *pq* (figura que sigue), pueden medirse horizontalmente, colocando primero dos reglas verticales *o*, *s* en línea recta con los objetos y tomando entonces el ángulo horizontal subtendido por las reglas.

**Los ángulos pueden medirse sin ningún instrumento**, así:
Mídanse 100 pies ó metros desde cada objeto y clávense estacas; mídase la distancia de una estaca á otra, la mitad de esta distancia será el seno de la mitad del ángulo para un radio de 100; y si dividimos esta cantidad por 100 tendremos el seno de esta mitad del ángulo para un radio 1 como está en la tabla. Así, supongamos que la distancia sea 80.64, entonces 40.32 es el seno de la mitad del ángulo y .4032 será el seno que, buscado en la tabla de senos le corresponderá en la columna de los ángulos el ángulo 23°47′ que multiplicado por 2 da 47°34 que será el ángulo deseado. Si algún obstáculo impide medir hacia los objetos, podemos medir directamente de ellos hacia el punto y prolongar ambas líneas, porque cuando dos líneas se cortan, los ángulos opuestos por el vértice son iguales. Se puede hacer una medida aproximada clavando tres alfileres verticales, separados algunas pulgadas, en un pedazo pequeño de cartón, fijo horizontalmente en la punta de un bastón. Los alfileres ocuparán las posiciones *nos* de la última figura.
Trácense entonces líneas de lápiz para unir los huecos de los alfileres y se medirá el ángulo con un transportador. Clavando un pedazo de cartón verticalmente sobre un árbol y trazando sobre aquél una línea horizontal pequeña, por medio de un nivel

**Advertencia.** Si como en la figura 3, fuese necesario medir la altura vertical *an* desde un punto *o*, más alto que *n*, ambos ángulos medidos en *o*, á saber: *son* y *soa* serán ángulos de depresión, es decir, más bajos que *o*. En este caso tenemos el lado *oa* como antes, el ángulo *noa* igual *soa* — *son*; y el ángulo *oan* = 180° — (*osa* (90°) y *soa*) para calcular *an* por medio del caso 1.°

O si como en la figura 4 deben ser tomados desde un punto *o* enteramente

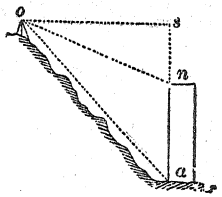


Fig. 3.

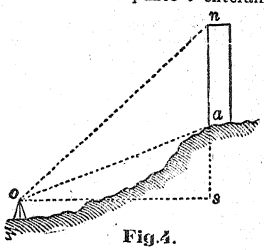

Fig. 4.

debajo del objeto *an* ambos ángulos *soa*, *son* serán ángulos de elevación, es decir por encima de la línea horizontal supuesta *os*. En este caso, tenemos en el triángulo *ona* el lado dado *oa*, como antes; el ángulo *aon* = *son*-*soa*, y el ángulo *ona* = 180° — (*osn* (90°) + *son*) para calcular *an* según el caso 1.°

Si el objeto *an*, como en la figura 5, en lugar de ser vertical está inclinado, y

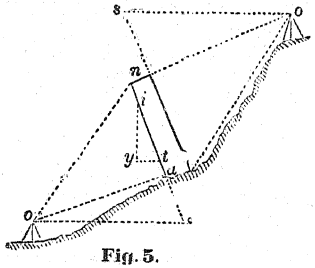

Fig. 5.

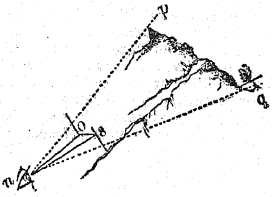
---

de aire, de carpintero, pueden medirse de la misma manera los ángulos verticales, de elevación y depresión. De esta manera el autor se ha aprovechado algunas veces de la puerta de una casa abriéndola hasta que su borde pase por el pico de alguna montaña cuya distancia conocía aproximadamente, pero sin tener idea de su altura. Respecto á las correcciones de refracción, etc., véase la tabla más próxima.



**Un triángulo cuyos lados están como los números** 3, 4 y 5, es rectángulo; y uno cuyos lados están como 7; 7; 9, 9 contiene un ángulo recto y dos ángulos de 45°, cada uno. Como es necesario frecuentemente trazar sobre el terreno ángulos de 45° y 90°, estas proposiciones se pueden usar con este fin, formando con un pedazo de cinta de agrimensor ó cadena uno de dichos triángulos y clavando una estaca en cada vértice

en lugar de su altura vertical deseamos saber su longitud *an*, debemos medir primero su ángulo *yti* de inclinación con la horizontal á cuyo ángulo cada uno de los ángulos *osn* (mídase de abajo ó de arriba) serán iguales. Para buscar este ángulo *yti*, suspéndase una plomada *iy* de cualquier longitud conocida en cualquier punto del objeto *an*, mídase *yt* horizontalmente y luego dígase:

$$yt : yi :: 1 : \text{tang } yti.$$

De la tabla de tangentes tómese el ángulo *yti* que corresponde á esta tangente y úsese este ángulo para los ángulos *osn* ú *osa*, en lugar del ángulo de 90° que

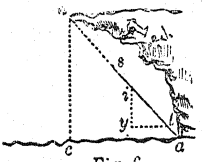


Fig. 6.

usamos en las figuras 3 y 4. Si el objeto, como la roca *an*, es curvo ó irregular, se debe colocar un bastón *as* inclinado en la dirección *an;* y mídase su ángulo *yt* de inclinación con la horizontal como antes y como antes también calcúlese la distancia *an*. Si se busca la altura vertical *cn*, debe encontrarse primero el punto *c* mirando hacia arriba á lo largo de una plomada sostenida sobre la cabeza.

**Ej. 3.° Encontrar la altura aproximada *sx* de una montaña** cuya cumbre es tan sólo visible porque se interponen árboles ú otros obstáculos y sólo se conoce la distancia *mi*. Para este caso, diríjase primero el instrumento horiz según *mh*, y mídase el ángulo *imx*. En el triángulo *imx* tenemos un lado *mi*, el ángulo medido *imx* y el ángulo *mix* que es recto, búsquese *ix* como en el caso 1.° Pero á este *ix* debemos agregarle *io*, igual á la altura *ym*, del instrumento sobre el

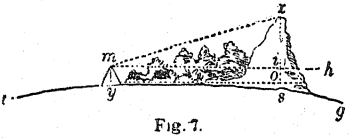

Fig. 7.

terreno y también *os*. Como *os* es debido solamente á la curvatura de la tierra, la cual es igual aproximadamente á cerca de 8 pulgadas, es decir, .667 de pies por cada milla (ó .126$^m$ por cada kilómetro) y aumenta como los cuadrados de las distancias siendo 4 veces 8 pulgadas en 2 millas (4 × .126$^m$ en dos kilómetros); 9 veces 8 pulgadas en 3 millas, etc. Esto lo disminuye en algo la refracción de la atmósfera que varía con la temperatura, humedad, etc.; y que tiende siempre á hacer aparecer el objeto *x* más alto de lo que realmente está. Como término medio esta ilusoria elevación alcanza como á una séptima parte del coeficiente de curvatura de la tierra ya citado, y también varía como ésta con los cuadrados de las distancias. Por consiguiente si sustraemos $^1/_7$ de 8 pulgadas ó de.667 de pies, tenemos el efecto combinado de la curvatura y refracción para una milla igual á 6.857 pulgadas ó .5714 de pies. (*N. del T.* Quitándole la séptima parte á .126$^m$ coeficiente de curvatura por kilómetro, resulta .108$^m$ por kilómetro para la corrección combinada de curvatura y refracción.) Para otras distancias tenemos la tabla siguiente, con cuyo uso nos evitamos la necesidad de hacer cálculos por separado, para la curvatura de la tierra y la refracción.

**Tabla de las cantidades que deben agregarse á las alturas por causa de la curvatura y refracción combinadas.**

| Dist. en yards. | Corrección en pies. | Dist. en millas. | Corrección en pies. | Dist. en millas. | Corrección en pies. | Dist. en millas. | Corrección en pies. |
|---|---|---|---|---|---|---|---|
| 100 | .002 | ¼ | .036 | 6 | 20.6 | 20 | 229 |
| 150 | .004 | ½ | .143 | 7 | 28.0 | 22 | 277 |

| 1828.0 | .2249 | 8.047 | 4.361 | 30.578 | 62.830 | 160.935 | 1743.511 |

**Por consiguiente**, para una persona cuya vista está á 1,567 metros sobre el nivel del mar, y ve un objeto, precisamente en el horizonte del mar, ese objeto estará como á 4,828 kil de distancia de él. (Véase la tabla última.)

**Una línea horizontal no es una línea á nivel** porque las líneas rectas no pueden estar á nivel puesto que la superficie terrestre es curva. La curvatura de la tierra aparece muy clara en una extensión de aguas tranquilas y éstas si están á nivel. Si en la figura 7 suponemos que la línea curva representa la superficie del mar, los puntos *t*, *y*, *s*, *g* están al mismo nivel entre sí. No siempre los puntos á nivel equidistan del centro de la tierra, porque el mar en los polos está como 13 millas (20,921 metros) más cerca del centro de la tierra que en el ecuador, sin embargo su superficie está en todas partes á nivel.

Cuando digamos **sobre y debajo**, significará sobre y debajo del nivel del mar. **Á nivel** significará paralelo á la curvatura del mar, y **horizontal** significa tangente al nivel del mar ó superficie de la tierra.

**Ej. 4.° Si la altura vertical *cd*, figura 8, es inaccesible.**

Colóquese entonces el instrumento para medir ángulos en cualquier punto *n* y plántense dos bastones en el plano vertical de *nd* cuyos extremos superiores *o*, *i*, estén en línea recta con *n* aun cuando no estén en la horizontal de *n*. Mídase *no*:

desde *n* mídanse los ángulos *ond*, *onc*. Muévase entonces el instrumento al punto donde está el bastón *o* y colóquese aquél á la altura y en el mismo lugar del punto *o*. Desde *o* mídanse los ángulos *iod*, *doc*. Hecho esto réstese el ángulo *ioc* de 180°, la diferencia será el ángulo *con*. Por consiguiente, en el triángulo *noc* tenemos un lado *no*, y dos ángulos *cno*, *con* para encontrar por medio del caso 1.°

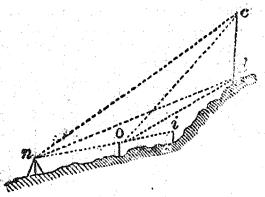

Fig. 8.

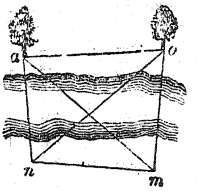

Fig. 9.

el lado *oc*. Además, réstese el ángulo *iod* de 180°, la diferencia será el ángulo *nod*; de modo que en el triángulo *dno* tenemos un lado *no* y los dos ángulos *dno*, *nod*, para encontrar aplicando el caso 1.° el lado *od*; y finalmente en el triángulo *cod* tenemos dos lados *co*, *od* y el ángulo comprendido *cod* para encontrar *cd* la altura vertical que se busca.

**Advertencia.** Si *cd* estuviera en un valle ó sobre un cerro y tuvieran que hacerse las observaciones desde un terreno alto ó bajo, las operaciones hubieran sido las mismas.

**Ej. 5.** Véase el ejemplo 10.

**Encontrar la distancia** *a*, *o*, fig. 9, **entre dos objetos inaccesibles.** Mídase un lado *mn*, en *n* mídanse los ángulos *anm* y *onn*; también en *m* mídanse los ángulos *omn*, *amn*. Hecho esto tenemos en el triángulo *anm*, un lado *mn*, fig. 9, y los ángulos *anm* y *nma*; entonces por el caso 1 podemos calcular el lado *an*. También en el triángulo *omn* tenemos un lado *mn* y los dos ángulos *omn*, *mno*; por el mismo caso 1 podemos calcular el lado *on*. Hecho esto tenemos en el triángulo *ano*, dos lados: *an*, *no*, y el ángulo comprendido *ano*; entonces por el caso 3 podemos calcular la distancia que buscamos. De paso podemos conocer la posición y dirección de la línea *ao* porque podemos saber el tamaño del ángulo *oan* en el triángulo *ano*, lo que nos permite hallar del lado acá una línea paralela á la línea *ao*. También se puede trazar en una escala conveniente la línea *mn* y los cuatro ángulos medidos y tomar luego en partes de la escala la distancia *ao*.

Si la posición de la línea inaccesible *cn*, fig. 10, fuere tal que se pudiera clavar una estaca *p* en la dirección *cn*, se procederá así: sitúese el instrumento en un punto conveniente *s* y mídanse los áng *psc*, *csn*; mídase también el áng *cps* y la dist *ps*. Entonces en el triángulo *psc*, encuéntrese la distancia *sc* por el caso 1.° Es claro que el áng externo *ncs* será igual á la suma de los internos opuestos *cps*, *psc* y tendremos en el triángulo *csn* un lado y dos ángulos para buscar el lado *cn* por el caso 1.°

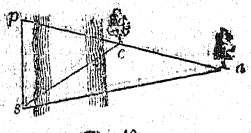

Fig. 10.

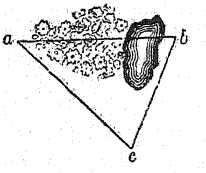

Fig. 11.

**Ej. 6. Medir una distancia** *ab* **cuyos extremos solamente son accesibles.** De *a* y *b* mídanse dos líneas cualesquiera *ac*, *bc* que se corten en *c*; y mídase también el áng *acb*. Tenemos entonces dos lados y el áng comprendido, resuélvase el triáng por el caso 3.°

**Ej. 7. Encontrar la altura vertical** *om* **de una montaña sobre un punto dado** *i*. Sitúese el instrumento en *i*, mídase *im*, póngase el instrumento

horizontal y mídase el áng *man*; como *anm* es de 90°, fig. 12, tenemos un lado *am* y dos áng *man*, *anm*, búsquese *mn* por el caso 1.° Agréguese la altura del instrumento *ai* igual *no*. Si la montaña es muy alta hágase la corrección combinada de curvatura y refracción como en el ejemplo 3, fig. 7.

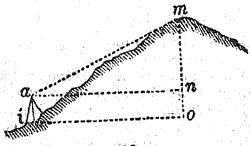

Fig. 12.

También puede colocarse el instrumento en el vértice *m* de la montaña y medir el áng *nma* de depresión en vez del áng *nam*.

**Advertencia 1.°** Si lo que conocemos es la altura *om* de la montaña, la medida del áng *nam* nos servirá para encontrar la distancia *ma* por el caso 1. Así en el ejemplo 2 si se conoce la altura *na*, los ángulos medidos en ese ejemplo nos facilitan el modo de deducir la distancia *ao*; lo mismo decimos para las figs. 3, 4, 5, 7, donde el procedimiento es tan claro que no se necesitan más explicaciones.

**Advertencia 2.° Para medir la altura de un objeto por su sombra.** Colóquese un bastón vertical en el suelo, mídase el largo de la sombra que arroja, también mídase el largo de la sombra del objeto. Entonces : el largo de la sombra del bastón es á la altura del bastón sobre el suelo, como la longitud de la sombra del objeto es á su altura. Si el objeto está inclinado, el bastón debe colocarse con la misma inclinación.

**Advertencia 3.° La altura de un objeto vertical** *mn*, fig. 12½, cuya distancia *rm* es conocida, puede encontrarse valiéndose de su **reflexión** en una vasija de agua, ó en un pedazo de espejo colocado perfectamente horizontal en *r*; porque *ra* es á la altura *ai*, de la vista sobre el reflector *r*, como *rm* es á la altura *mn* del objeto sobre *r*.

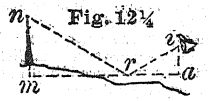

Fig. 12¼

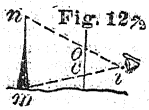

Fig. 12¾

**Advertencia 4.°** Supongamos que *oc*, fig. 12½, sea una estaca plantada ó una vara sostenida verticalmente por un asistente. Entonces, coloquémonos á una distancia propia detrás de ella y manteniendo la vista fija háganse marcas en *o*, *c*, donde las visuales *in*, *im*, cortan la vara ó bastón *oc* y entonces : *ic* es á *co* como *im* á *mn*.

Los ejemplos siguientes pueden sustituir á un procedimiento trigonométrico y serán útiles á veces en caso de no tener á la mano una tabla de senos para hacer los cálculos trigonométricos.

**Ej. 8. Encontrar la distancia** *ab* **en la cual sólo un extremo es acce-**

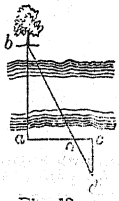

Fig. 13

**sible.** Clávese una estaca en cualquier punto conveniente *a*; en *a* trácese un ángulo cualquiera *bac*. En la línea *ac*, en cualquier punto conveniente *c* clávese una estaca

y en *c* trácese un ángulo *acd*, igual al *bac*. En la línea *cd* y en cualquier punto conveniente, *d*, clávese una estaca. Luego parándose en *d* y mirando hacia *b* colóquese una estaca *o* en línea con *db* y que quede situada al mismo tiempo en línea *ac*, mídanse las distancias *ao*, *oc*, *cd*; y entonces según el principio de los triángulos semejantes

$$oc : cd :: ao : ab.$$

También puede procederse de este otro modo, fig. 14 : siendo la distancia que se ha de medir *nh*, colóquese una estaca en *n*; y trácese el ángulo $hnm = 90°$; á cualquiera distancia conveniente *nm* colóquese una estaca *m*; hágase el áng $hmy = 90°$ y colóquese una estaca en *y* en línea con *hn*. Mídase *my*, *nm*, y entonces según el principio de los triángulos semejantes tenemos $ny : nm = nm : nh$.

**Otro modo** : fig. 14. Trácese el ángulo $hnm = 90°$ colocando una estaca *m* á cualquier distancia conveniente *nm*. Mídase *nm* y también el ángulo *nmh*. Búsquese la tangente de *nmh* por medio de la tabla y multiplíquese esta tangente natural por *nm*; el producto será *nh*.

**Otro modo** : Trácese el ángulo $hnm = 90°$, desde *m* mídase el ángulo *nmh*, y trácese el ángulo *nmy* igual al ángulo *nmh*; colóquese una estaca en *y* en línea con *hn*. Entonces $ny = nh$.

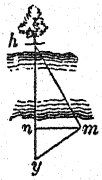

Fig. 14.

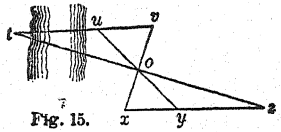

Fig. 15.

**Ó sin medir ningún ángulo, así** : Siendo la distancia *tu* la que quiere medirse tómese *uv* de cualquier longitud en línea recta, con *tu* mídanse *vo* y *ox* iguales. Mídanse *ou*; y *o y* iguales también entre sí. Colóquese una estaca *z*, en línea recta con *xy*, y *to* : entonces *yz* será igual á *tu* y paralela.

**También puede hacerse sin medir ningún ángulo, así** : Clávense dos estacas *t* y *u* en línea con el objeto *s*, fig. 16. Desde *t* márquese una distancia *tx* en cualquiera dirección; desde *u* trácese *uw* paralela á *tx* colocando el punto *w* en línea recta con *xs*. Hágase *uv* igual *tx*, mídase *wv*, *vx*, *tx* y entonces

$$wv : vx :: xt : ts.$$

**Ó así** : * trácese desde un punto *o* la línea *oc* en ángulo recto con *oa* y búsquese en esa línea *oc* un punto *c* desde donde el ángulo *oca* sea de 84° 17′ de manera que el ángulo *oac* resulta 5° 43′; mídase ahora *oc* y *ao* será $= 10 \times oc$ con un error en exceso de 1.06 por 1,000.

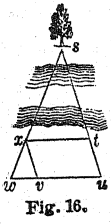

Fig. 16.

**Ej. 9. Encontrar la distancia *ab* cuyos extremos sólo son accesibles**. Trácese desde *a* el ángulo *bac* y desde *b* el ángulo *abd*, cada uno de 90°.

*N. del T. — Aquí discrepamos del autor, pues siendo inaccesible uno de los extremos de la línea, en este caso el *a*, todas las operaciones deben hacerse del lado *oc* y por eso hemos variado las operaciones en este supuesto sin cambiar el sistema de entrar con un ángulo fijo; lo que no nos parece práctico.

Háganse *ac*, *bd*, iguales entre sí. Entonces *cd*=*ab*. También puede considerarse *ab* como la distancia á través del río en las figs. 13, 15 ó 14; y puede encontrarse por los procedimientos ya empleados en dichos casos. O de otro modo, mídase cualquier distancia *ao*, fig. 17, y constrúyase *on* igual y en línea recta con *ao*. Mídase también *bo* y hágase *om* igual y en línea recta de *ob*. Entonces *mn* será paralela é igual *ab*.

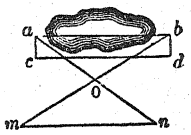

Fig. 17.

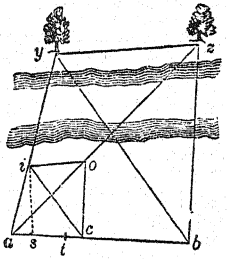

Fig. 18.

**Ej. 10.** Véase el ejemplo 4.º

**Encontrar la distancia y dirección de la línea enteramente inaccesible** *yz*. En dos puntos convenientes *ab*, desde donde los puntos *yz* puedan verse, clávense estacas. Tenemos entonces los cuatro ángulos de una figura de cuatro lados en la cual están dadas las direcciones de tres de sus lados y de sus dos diagonales. Estos datos nos facilitan el trazar sobre el terreno una pequeña figura de cuatro lados semejante á la grande. Así, en la línea *ab* colóquese una estaca *c* y hágase *co* paralela á *bz* situando el punto *o* al mismo tiempo en la diagonal *az*. Desde *c* hágase *ci* paralela á *by*; situando el punto *i* al mismo tiempo en la línea *ay*, entonces *io* será paralela á *yz*. Mídase *ac*, *ab*, *io*, y entonces por el principio de las figuras semejantes

$$ac \ : \ ab \ : : \ io \ : \ yz.$$

Si *yz* fuere una línea visible tal como una cerca ó camino, podríamos desde *a* dividirla en cualquier número de partes. Por ejemplo, si deseamos colocar una estaca en la mitad de *yz*, colóquese primero una en la mitad de *io*; y parándose en *a* por medio de señales diríjase por la estaca situada en el medio de *io* una visual, y donde ésta corte la línea *yz* será el punto medio de *yz* que desde *a* queda determinado así.

Para encontrar sobre *ab* un punto *t* de una perpendicular á la línea *yz* levantada en *y*; hágase primero *ois*=90º y mídase *as*. Entonces

$$oi \ : \ as \ : : \ yz \ : \ at.$$

**Ej. 11. Encontrar la posición de un punto** *n*, **fig. 19, por medio** de dos ángulos *anb*, *bnc*, tomadas desde él á los tres objetos *a*, *b*, *c*, cuyas posición y distancias entre sí son conocidas.

El uso de este problema es más frecuente en cartas marinas que en la mensura

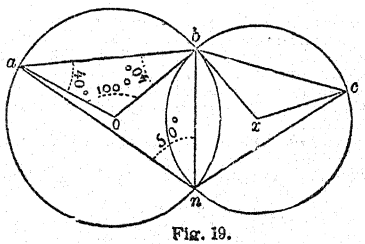

Fig. 19.

de terrenos. Se emplea principalmente para determinar la posición *n* de un bote desde el cual se han hecho sondas á lo largo de la costa. Cada vez que el bote se

mueve de un puesto á otro para sondear nuevamente se hace necesario practicar nuevas observaciones en cada punto con el objeto de fijar su posición en la carta. Cada observación consiste en la medida, por medio de un sextante, de los dos ángulos *anb*, *bnc*, á las señales *a*, *b*, *c*, fijadas de antemano en la costa. Cuando sea practicable tomar las observaciones dirigiendo visuales al bote al mismo instante por medio de dos observadores en la costa, situados en dos de las estaciones, debe preferirse este método. El bote hará entonces una señal en el momento que deban hacerse las observaciones. El método más expedito para fijar el punto *n* sobre el mapa, es trazar tres líneas formando los dos ángulos y prolongarlas indefinidamente en un pedazo de papel transparente. Colóquese el papel sobre el mapa y muévase éste hasta que las tres líneas pasen por las tres estaciones *a*, *b*, *c*; márquese entonces el punto *n* dondequiera que quede.

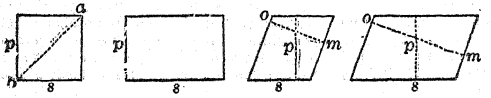
En lugar del papel transparente se puede usar el instrumento llamado marcador de estaciones, cuando hay muchos puntos que marcar.

Pero la posición del punto puede encontrarse, quizás con más exactitud, describiendo dos círculos, como en la fig. 19, que pase cada uno por el punto *n* y por dos de los otros tres puntos; encontrando luego los centros, *o*, *x*, de dichos dos círculos. Esto es muy sencillo. Sabemos que el ángulo *aob* en el centro de un círculo es dos veces mayor que cualquier ángulo *anb* en la circunferencia del mismo círculo cuando éstos están subtendidos por la misma cuerda *ab*. Por consiguiente, si el ángulo *anb* observado desde el bote es de 50°, el ángulo *aob* debe ser de 100° y como la suma de los tres ángulos de un triángulo es 180° los dos ángulos *oab*, *oba*, valen juntos $180° - 100° = \frac{80°}{2}$, y como los dos lados *ao*, *bo*, son iguales (siendo radios del mismo círculo), los ángulos *oab*, *oba* son iguales entre sí y cada uno igual á $80°/_2 = 40°$. Por consiguiente, tenemos solamente que trazar sobre el mapa, en *a* y *b*, dos ángulos de 40°, el punto *o* de intersección será el centro. Procédase de la misma manera con el ángulo *bnc* para encontrar el centro.

La intersección de los dos círculos en *n* será el punto que se busca.

## PARALELOGRAMOS

**Cuadrado. Rectángulo. Losango. Paralelogramo.**



Un paralelogramo ó rombo es una figura plana encerrada por cuatro líneas rectas y paralelas las opuestas. No hay sino los cuatro indicados en las figuras anteriores. En el cuadrado y el *losango* los cuatro lados son iguales; en el *paralelogramo rectángulo* sólo los lados opuestos son iguales. En cualquier paralelogramo los cuatro ángulos suman cuatro ángulos rectos ó 360° y los dos ángulos diagonales opuestos son iguales entre sí; por consiguiente, teniendo un ángulo pueden encontrarse fácilmente los otros tres. En un cuadrado ó un rectángulo cada diagonal divide á cada uno de los ángulos en dos partes iguales, pero en los otros dos paralelogramos no sucede así.

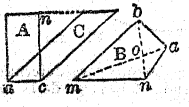
**Para encontrar el área de cualquier paralelogramo.** Multiplíquese cualquier lado, *s*, por la altura *p* tomada perpendicularmente al lado *s* ó multiplíquense entre sí dos lados y el seno del ángulo comprendido.

**La diagonal *ab* de cualquier cuadrado** es igual á un lado multiplicado por 1.41421, y un lado es igual á la diagonal multiplicada por .707107.

**El lado de un cuadrado igual en superficie á un círculo dado** es igual al diámetro × .886227.

**El lado del mayor cuadrado** que puede inscribirse en un círculo dado es igual al diámetro × .707107.

El lado de un cuadrado multiplicado por 1.51967 da el lado de **un triángulo**



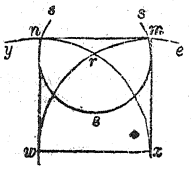
**equilátero** de la misma área. **Todos los paralelogramos** como A, C, **que tienen iguales bases** *ac*, é igual altura *nc*, tienen iguales áreas y el área de cada uno es dos veces la de un triángulo que tenga la misma base y la misma altura. **El área de un cuadrado inscrito en un círculo** es igual á dos veces el cuadrado del radio.

**En todo paralelogramo** los cuatro cuadrados trazados sobre sus lados tienen una área igual á los de los dos cuadrados trazados en sus 2 diagonales. Si se traza **un cuadrado grande** en la diagonal *ab* de un cuadrado más pequeño su área será dos veces la del cuadrado pequeño. **Cualquiera de las diagonales de cualquier paralelogramo** lo dividen en dos triángulos iguales y las 2 diagonales lo dividen en 4 triángulos de iguales áreas. **Las dos diagonales de cualquier paralelogramo** se dividen entre sí en dos partes iguales. **Cualquiera línea recta trazada por el centro** del paralelogramo lo divide en dos partes iguales.

**Advertencia 1.ª El área de cualquiera figura, como B formada por cuatro líneas rectas,** puede encontrarse así: Multipliquense las dos diagonales *am*, *nb*, y el seno del ángulo menor *aob*, ó *nom* formado por la intersección de ellas. Divídase el producto por 2. Esto es útil en la mensura de terrenos cuando los obstáculos, como á menudo sucede, hacen difícil la medida de los lados de la figura, mientras que es fácil medir las diagonales y después encontrar su punto de intersección *o* y medir el ángulo que se requiere. **Pero si se tiene que trazar la figura, las partes** *oa*, *ob*, *on*, *om* de las diagonales deben ser medidas también.

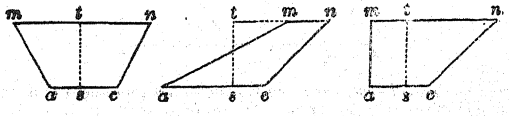
**Advertencia 2.ª Los lados de un paralelogramo ó triángulo y los de muchas otras figuras pueden encontrarse cuando sólo se conoce el área y los ángulos,** así: Supongamos que uno de los lados sea 1 y calcúlese cuál sería su área para el lado 1 y dígase: la raíz cuadrada del área así encontrada es á este lado 1 como la raíz cuadrada del área dada es al lado correspondiente de la figura que se busca.

**En una línea dada** *wx* **trazar un cuadrado** *wxnm*. De *w*, y de *x*, con radio *wx* descríbanse los arcos *xry*, *wre*. Desde su intersección *r*, y con un radio igual á ½



*wx*, descríbase *sss*. Desde *wx* trácese *wn*, *xm* tangente á *sss*, hasta llegar á los otros arcos y únase *n* con *m*.

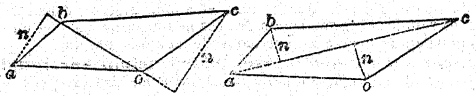
## TRAPECIOS



Un trapecio *acnm* es un cuadrilátero que tiene dos lados paralelos *ac*, *nm*.

**Para encontrar el área de cualquier trapecio.** Súmense los dos lados *ac*, *nm*, multipliquese la suma por la distancia *st* y divídase el producto por 2. Véanse las reglas siguientes para los cuadriláteros en general que son todas aplicables á los trapecios y véanse también las advertencias después de los paralelogramos.

**Un** cuadrilátero *abco* es cualquiera figura terminada por cuatro líneas rectas.



**Para encontrar el área de un cuadrilátero conociendo la diagonal** *bo* ó la *ac* **que une dos ángulos opuestos y también las dos perpendiculares** *nn* **bajadas desde los otros dos ángulos** : súmense estas dos perpendiculares, multiplíquese la suma por la diagonal y divídase el producto por 2.

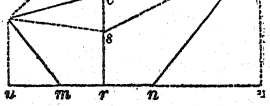
**Teniendo los cuatro lados y uno de los dos pares de ángulos opuestos como** *abc, aoc*, ó bien *bao, bco*, considérese el cuadrilátero dividido en dos triángulos en cada uno de los cuales se conocen dos lados y el ángulo comprendido. Búsquese el área de cada uno de estos triángulos como se ha indicado ya en el capítulo « Triángulos » y súmense.

**Teniendo los cuatro ángulos y un par de lado supuestos.** Supongamos que se conoce un lado y los dos ángulos de sus extremos. Si la suma de estos ángulos excede de 180° réstese cada uno de ellos de 180° y hágase uso de estas diferencias en lugar de los ángulos mismos. Considérense entonces este lado y sus dos ángulos adyacentes (ó las dos diferencias, según sea el caso) como los de un triángulo y búsquese su área como se ha indicado en el capítulo « Triángulos ». Hágase lo mismo con el otro lado dado y sus dos ángulos adyacentes (ó sus diferencias); réstese la menor de las áreas encontradas así de la mayor y la diferencia será el área que se busca.

**Teniendo tres lados y los dos ángulos comprendidos.** Multiplíquese el lado intermedio por uno de los lados adyacentes; multiplíquese el producto por el seno del ángulo comprendido entre estos dos lados, llámese el resultado *a*. Hágase lo mismo con el mismo lado intermedio, el otro lado adyacente y el seno del otro ángulo comprendido y llámese *b* al resultado. Súmense los dos ángulos, búsquese la diferencia entre esa suma y 180°, sea mayor ó menor, búsquese el seno de esa diferencia, multiplíquense los dos lados dados opuestos el uno al otro; multiplíquese el producto por el seno que se acaba de encontrar y llámase *c* el resultado. Súmense los resultados *a, b*, si la suma de los dos ángulos dados es menor de 180°, réstese *c* de la suma $a+b$ y la mitad de la diferencia será el área del cuadrilátero. Pero si la suma de los dos ángulos dados es mayor que 180° súmense los tres resultados *a, b, c* y la mitad de dicha suma será el área.

**Teniendo las dos diagonales y uno de los dos ángulos formados por la intersección de ellas.** Véanse las advertencias después del párrafo paralelogramos.

**En las medidas de banqueos y terraplenes en los ferrocariles** se presenta muy frecuentemente la medida del cuadrilátero *lmno* y también la de las



dos figuras de 5 lados *lmnot, lmnos*, en las cuales *nm* representa el ancho de vía, *rs, rc, rt*, lo que hay que banquear en el centro; *lu, ov* la altura del talud inferior y superior sobre la vía; y *lm, no* los dos taludes.

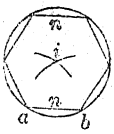
La misma regla general para medir las áreas se seguirá en estas tres figuras; á saber : multiplíquese la anchura del extremo horizontal *uv* por la mitad de la altura en el centro *rs, rc*, ó *rt*, según sea el caso. Multiplíquese también una cuarta parte del ancho de vía *mn* por la suma de las dos alturas *lu, ov*, súmense los dos productos y la suma será el área que se busca. Esta regla es aplicable cuando tengan, ó no, los dos taludes *lm, no*, la misma inclinación.

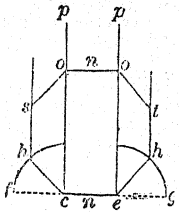
**En los trabajos de ferrocarril, etc.**, las dimensiones que acabamos de ver de la sección media del prismoide; como el ancho medio horizontal, altura del centro y de los taludes,es la semisuma de esas mismas dimensiones en los extremos del sólido y pueden obtenerse sin necesidad de medidas directas.

**Para trazar un exágono cuyos lados deban ser iguales á una línea dada,** *ab*. De *ab* con un radio *ab* descríbanse dos arcos; desde su inter-

sección *i*, con el mismo radio descríbase un círculo; alrededor y sobre su circunferencia váyase colocando el mismo radio.

Lado de un exágono $= n \times .57735$.

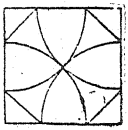


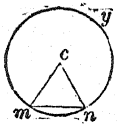


**Para trazar un octógono cuyos lados sean iguales á una línea dada, *ce*.** De *c* y de *e* trácense dos perpendiculares *cp*, *ep*, prolónguese también *c*, *e* hacia *f*, *g* y de *c*, *e* con un radio igual *ce* trácense dos cuadrantes y búsquense sus centros *hh*; únanse *ch*, *eh*; trácense *hs*, *ht* paralelas á *cp* é iguales á *ce*; háganse *co*, *eo*, iguales cada una á *hh* únanse *co*, *os*, *ot*.

Lado de un octógono $= n \times .41421354$.

**Para trazar un octógono en un cuadrado dado** : desde cada ángulo del cuadrado y con un radio igual á la mitad de su diagonal, descríbanse cuatro arcos y únanse los puntos en los cuales cortan los lados del cuadrado.





**Para trazar cualquier polígono regular de lados iguales á *mn*** ; divídase á 360° por el número de lados, réstese el cociente de 180°, divídase la diferencia por 2. Esto dará el ángulo *cmn*, ó *cnm*. En *nm* trácense estos ángulos por medio de un transportador, los lados de estos ángulos se encontrarán en un punto *c* desde el cual se describirá el círculo *mny*, sobre su circunferencia se irán colocando distancias iguales á *mn*.

**En cualquier círculo *mny* trazar cualquier polígono regular.** Divídase á 360° por el número de lados, el cociente será el ángulo *mcn* del centro. Trácese el ángulo por medio de un transportador y su cuerda *mn* será un lado que se va colocando alrededor de la circunferencia.

**Para reducir cualquier polígono como *abcdefu*, á un triángulo de la misma área.** Prolongamos el lado *fa* hacia *w* y trazamos *bg* paralela á *ca*

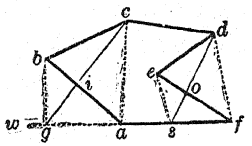


Fig. 1.

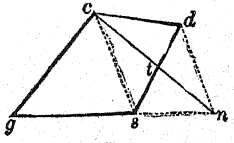

Fig. 2.

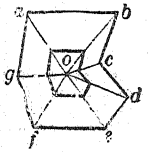
y trazamos *ge*; obtenemos 2 triángulos *abc*, *age*, ambos de la misma base *ca* y de la misma altura, puesto que sus vértices están entre las dos paralelas *ac*, *gb*. Pero la parte *aci* es común á ambos; por tanto las partes restantes *icb* de uno *iga* del otro serán iguales entre sí. Ahora si la parte *icb* se la quita al polígono y se le pone la parte *iga*, el polígono *gfedcig* tendrá la misma área que *afedcba*, pero no tendrá sino cinco lados mientras que el otro tiene seis. Además, si *se* se traza paralela á *df* y se une *i* con *s* tenemos sobre la misma base *es*, y entre las mismas paralelas *es*, *df* los dos triángulos iguales *esd*, *esf* con la parte *eos* común á ambos y por consiguiente la parte restante *cod* de uno, *osf* del otro serán iguales. Por tanto si se quita *osf* del polígono y se agrega *eod*, el nuevo polígono *gsdc*, fig. 2,

tendrá la misma área que *gfedc;* pero no tiene sino cuatro lados, mientras que el otro tiene cinco. Finalmente, si se prolonga *gs*, fig. 2, hacia *n*, se traza *dn* paralela á *cs*, y se une *c* con *n* tenemos en la misma base *cs*, y entre las mismas paralelas *cs*, *dn* los triángulos equivalentes *csn*, *csd*, con la parte *cst* común á ambos; por tanto si quitamos á *cdt* del polígono y le agregamos *stn* tenemos el triángulo *gnc* igual al polígono *gsdcg*, fig. 2, ó á *afedcba*, fig. 1. Este método es aplicable á polígonos de cualquier número de lados.

**Reducir una figura grande *abcdefg* á una semejante más pequeña.** Desde cualquier punto interior *o* (será mejor mientras más cerca del centro esté) trácense líneas á todos los ángulos *abc*, etc. y únanse estas líneas con otras para-

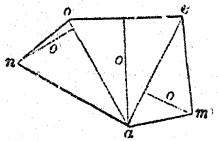


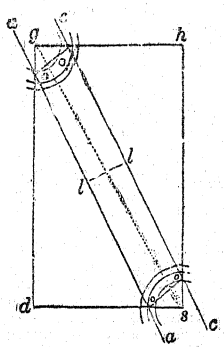
lelas á los lados de la figura. Si por el contrario se quiere aumentar una figura pequeña, trácense de cualquier punto *o* dentro de ella, líneas que se prolonguen más allá de sus ángulos y únanse estas líneas por otras paralelas á los lados de la figura pequeña.

**Para reducir un mapa á una escala menor.** El mejor método es dividir el mapa grande en cuadrados por medio de líneas ligeras trazadas con lápiz muy suave y trazar luego el mapa reducido sobre un papel dividido en cuadrados menores. El compás de división ayudará mucho al fijar puntos situados dentro de los cuadrados. Si el mapa grande ha sufrido por el dibujo y el continuo borrar, se pueden tender hilos para formar los cuadros.

**En una figura rectangular** *ghsd*, encontrar los puntos *oooo* sobre sus lados y á igual distancia de los ángulos *gs;* para inscribir un rectángulo diagonal *oooo* de una anchura dada *ll*. Desde *g*, *s*, como centros descríbanse varios arcos concéntricos, como están en la figura. Trácense sobre papel transparente dos líneas *aa*, *cc* separadas una distancia *ll*, y colocando estas líneas sobre el tablero muévanse hasta que se vea por los arcos que las cuatro distancias *go*, *go*, *so*, *so*, son iguales. En lugar del papel transparente se puede usar una tira de papel común del ancho *ll*.

**Advertencia.** Muchos problemas que de otro modo serían muy difíciles pueden resolverse de modo análogo con una exactitud suficiente para casos prácticos **por medio del papel transparente.**

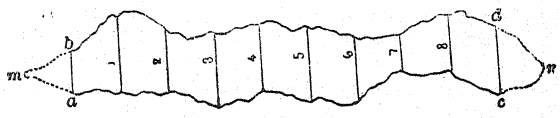




**Para encontrar el área de cualquier polígono irregular** *anbcm*. Divídase éste en triángulos como *anb*, *amc*, *abc*, búsquense las alturas *o*, *o*, *o*. de cada uno de ellos entre su base *ab*, *ac*, *bc* y el ángulo opuesto *n*, *m;* multipli-

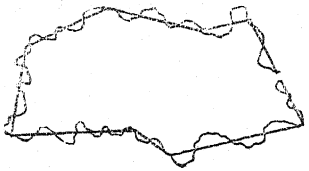
quese cada base por la altura respectiva, súmense todos los productos juntos y divídase por 2.

**Para encontrar aproximadamente el área de una figura muy larga, irregular como** *abcd*. Entre sus extremos *abcd* márquense iguales distancias (mientras más cortas sean más exacto será el resultado), trácense líneas paralelas intermedias 1, 2, 3, etc. Mídanse las longitudes de estas líneas



intermedias, súmense; á esta suma agréguese la semí suma de los dos anchos *ab*, *cd* en los extremos; multiplíquese la suma total por uno de los espacios iguales entre las líneas paralelas y el producto será el área que se busca. Esta regla se aplica del mismo modo si ambos, ó uno de los extremos, terminan en punta como *m*, *n*. En el último de estos casos los anchos *ab*, *cd*, entrarán á sumarse con las líneas intermedias y es claro que la mitad de la anchura en los dos extremos será *o*.

**Encontrar el área de una figura cuyo perfil es extremadamente irregular.** Trácense líneas alrededor de ella que le agreguen á la figura (tan aproximadamente como pueda juzgarse á la vista) tanto espacio como el que le quiten á la misma figura. El área de la figura nueva que se forma se hace de



este modo igual á la figura irregular y puede calcularse dividiéndola en triángulos, etc. Usando un pedazo de hilo fino puede encontrarse la adecuada posición para las nuevas líneas limítrofes antes de trazarlas. Para medir áreas pequeñas é irregulares en un dibujo se colocará sobre él un pedazo de papel transparente dividido cuidadosamente en pequeños cuadros cada uno de una área dada, digamos de 10, 20 ó 100 pies ó decímetros, etc., cuadrados y luego se contarán todos los cuadrados enteros y se agregarán las fracciones de cuadrados apreciadas al ojo.

## CÍRCULOS

**Un círculo** es la superficie comprendida por una curva reentrante llamada circunferencia cuyos puntos equidistan de otro interior llamado **centro**. Toda línea recta que pasa por el centro y termina por ambos lados en la circunf se llama **diámetro** del círculo. Toda línea recta que va del centro á la circunf se llama **radio**.

La relación de la circunf al diám ó de la semicircunf al radio, circunf ÷ diám se llama $\pi$ (**pi**).

$$\pi = 4\,(1 - 1/3 + 1/5 - 1/7 + 1/9 - \text{etc.})$$

$\pi$ es inconmensurable, no tiene expresión aritmética exacta. Ha sido determinado hasta varios cientos de cifras decimales.

**Valores aproximados de $\pi$; $\pi = x + a/a$:**

| $x$ | $a$ | $x$ | $a$ |
|---|---|---|---|
| 3.141 592 653 6. | — 307,788,000,000 | 355 ÷ 113 .. | — 11,776,700 |
| 3.141 592 65.... | ... + 875,085,000 | 377 ÷ 120 .. | ... — 42,447 |
| 3.141 593..... | ..... — 9,069,000 | 366 ÷ 116.6.. | ... + 13,576 |
| 3.141 6..... | ..... — 427,637 | 22 ÷ .. | .... — 2,485 |

## Funciones de $\pi$.

| | Logarit. | | Logarit. |
|---|---|---|---|
| $\pi = 3.14159265$ | 0.497 1499 | $2/\pi = 0.636620$ | $\bar{1}.803\ 8801$ |
| $\pi/2 = 1.57079632$ | 0.196 1199 | $3/\pi = 0.954930$ | $\bar{1}.979\ 9714$ |
| $\pi/3 = 1.04719755$ | 0.020 0286 | $\pi^2 = 9.869604$ | 0.994 2997 |
| $\pi\sqrt{2} = 4.442883$ | 0.647 6649 | $\pi^3 = 31.00628$ | 1.491 4496 |
| $\pi/\sqrt{2} = 2.221442$ | 0.346 6349 | $\sqrt{\pi} = 1.772454$ | 0.248 5749 |
| $1/\pi = 0.318310$ | $\bar{1}.502\ 8501$ | $1/\sqrt{\pi} = 0.564190$ | $\bar{1}.741\ 4251$ |

**Para múltiplos de** $\pi$, véase « Circunf » en las tablas de los *Círculos* que siguen.

**Radio,** $R$; **Diámetro,** $D$; **Circunf,** $C$; **Área,** $A$.

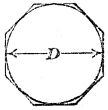
$$R = \frac{D}{2} = \frac{C}{2\pi} = \sqrt{\frac{A}{\pi}}; \qquad D = 2R = \frac{C}{\pi} = 2\sqrt{\frac{A}{\pi}};$$

$$C = 2\pi R = \pi D = 2\sqrt{\pi A}; \qquad A = \pi R^2 = \frac{\pi}{4} D^2 = \frac{C^2}{4\pi} = \frac{DC}{4}.$$

## RELACIONES DEL CÍRCULO CON OTRAS FIGURAS

**Polígono circunscrito,** regular ó irregular.

$$\frac{\text{Area del circ}}{\text{Area del políg}} = \frac{\text{circunf del círc}}{\text{perímetro del políg}}.$$



**Triángulo equilátero de igual área.** D=diám del círc.

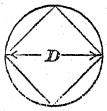
Lado del triáng $= D\sqrt{\pi} \div \sqrt[4]{3} = 1.34677\ D.$

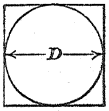
**Cuadrado de la misma área.**

Lado del cuad= .88623 × diám del círc.
Diám del círc =1.12838 × lado del cuad.

**Cuadrado inscrito.** D=diám del círc.

Lado del cuad $= D\sqrt{\frac{1}{2}} = .7071\ D.$
Area del cuad = 2 × radio² (del círculo)
Radio del círc = ½ × diagonal del cuad
$= \sqrt{\frac{1}{2}} \times$ lado del cuad = .7071 × lado.





**Cuadrado circunscrito.**

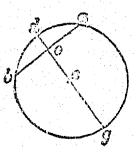
A=área del cuad; $a$=área del círc.

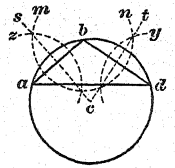
$$A = \frac{4}{\pi} a = 1.2732\ a; \qquad a = \frac{\pi}{4} A = .7854\ A.$$

## PROBLEMAS RELATIVOS Á LOS CÍRCULOS

**Encontrar el diám *dg* y el centro *c* de un círculo dado.**

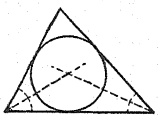
Trácese una cuerda cualquiera *ab* y en su centro *o* levántese un diám perpendicular *dg*. Encuéntrese el centro *c* de este diám. O véase más abajo.

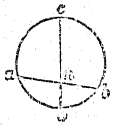


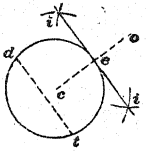


**Describir una circunf que pase por tres puntos *abc* que no están en línea recta, por ej. : los tres vértices de un triángulo.** Unanse los puntos por líneas *ab*, *bd*. Desde *b* con cualquier radio conveniente, se traza el arco *mn* y de *a*, y, *d* con el mismo radio trácense los arcos *y*, *z*; entonces las dos líneas *cs*, *ct* que unen las intersecciones de estos arcos, se cortarán en el centro *c* del círculo.

**Inscribir un círculo en un triángulo.** Trácense dos líneas *bisectrices* de dos cualesquiera de los ángulos; donde estas dos líneas se cortan está el centro del círculo.



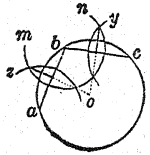


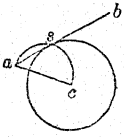


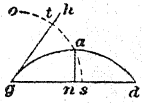
En **dos cuerdas** cualesquiera *ab*, *oc*, que se cortan en *n* se tiene que *on* : *nb* :: *an* : *nc*; por tanto, *nb*×*an*=*on*×*nc*. Es decir, el producto de los dos segmentos de una de las cuerdas=al producto de los dos segmentos de la otra.

**Tangentes.** Aquí la tang es simplemente una línea indefinida que toca á la circunf en un punto; no es la tang trigonométrica.

**Para trazar una tang *iei* á un circ por un punto dado *e* de su circunf**; trácese el radio *ce* á ese punto, hágase *eo*=*ec* de *c* y *o* con cualquier radio mayor que la mitad de *co*, descríbanse dos pares de arcos *i*, *i*, y únanse sus intersecciones *i*, *i*. O bien de *e*, trácense dos distancias cualesquiera iguales *ed*, *et*, y trácese *i*, *i*, paralela á *dt*.







**Para trazar una tang *asb* á un circ desde un punto afuera del circ**; únase *a* con *c*, centro del circ. Sobre *ac* trácese una semicircunf y por la intersección *s* trácese *asb*.

**Para trazar una tang *gh* á un arco circular *gad* cuya flecha es *na*.** Con el radio *ga*, descríbase un arco *sao*, hágase *ta*=*sa*; por *t* tírese *gh*.

## TABLA DE CÍRCULOS

**Los diámetros se dan en unidadades y décimos.**

| Diám. | Circf. | Area. | Diám. | Circf. | Area. | Diám. | Circf. | Area. |
|---|---|---|---|---|---|---|---|---|
| 0.1 | .314159 | .007854 | 6.3 | 19.79203 | 31.17245 | 12.5 | 39.26991 | 122.7185 |
| .2 | .628319 | .031416 | .4 | 20.10619 | 32.16991 | .6 | 39.58407 | 124.6398 |
| .3 | .942478 | .070686 | .5 | 20.42035 | 33.18307 | .7 | 39.89823 | 126.6769 |
| .4 | 1.256637 | .125664 | .6 | 20.73451 | 34.21194 | .8 | 40.21239 | 128.6796 |
| .5 | 1.570796 | .196350 | .7 | 21.04867 | 35.25652 | .9 | 40.52655 | 130.6981 |
| .6 | 1.884956 | .282743 | .8 | 21.36283 | 36.31681 | 13.0 | 40.84070 | 132.7323 |

## Ejemplos.

**Diám**=3.12699
**Circunf**= Suma de
Circ para el diám de 3.1 = 9.738937
— .02 = .062832
— .006 = .018850
— .0000 = .002827
— .00009= .000283
9.823729

**Circunf**=9.823729
**Diám** = Suma de
Diám p' la circ. de 9.738937=3.1
.084792
— .062832= .02
.021960
— .018850= .006
.003110
— .002827= .0009
.000283
— .000283= .00009
3.12699

## ARCOS CIRCULARES

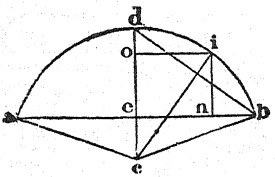

Fig. 1

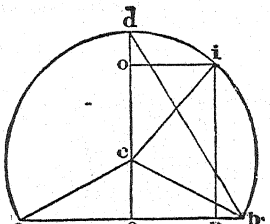

Fig. 2.

Las reglas establecidas para la fig. 1 se aplican á todos los arcos iguales ó *menores* que una semicircunferencia.

Las reglas para la fig. 2 se aplican á todos los arcos iguales ó *mayores* que una semicircunferencia.

### Cuerda, *ab*, de todo arco *adb*.

$= 2 \times \sqrt{\text{radio}^2 - (\text{radio} - \text{flecha})^2}$. Fig. 1.

$= 2 \times \sqrt{\text{radio}^2 - (\text{flecha} - \text{radio})^2}$. Figs. 2.

$= 2 \times \sqrt{\text{flecha} \times (2 \times \text{radio} - \text{flecha})}$. Figs. 1 y 2.

$= 2 \times \text{radio} \times \text{sen } \frac{1}{2}\ acb$. Figs. 1 y 2.

$= 2 \times \dfrac{\text{flecha}}{\text{tangente } abd^*}$. Figs. 1 y 2.

$= 2 \times db\,\S \times \cos abd^*$. Figs. 1 y 2.

$= 2 \times \sqrt{db^{\S\,2} - \text{flecha}^2}$. Figs. 1 y 2 **.

= aproximadamente $8 \times db^{**} - 3 \times$ longitud del arco *adb* fig. 1.

### Longitud del arco *adb*.

$= 2\pi$ radio $\times \dfrac{\text{arco } adb \text{ en grados}}{360}$. Figs. 1 y 2.

= .01745 × radio × arco *adb* en grados. Figs. 1 y 2.

= Circunferencia del círculo — longitud del arco pequeño que subtende el ángulo *acb*, fig. 2.

= aproximadamente $\dfrac{8 \times db\,\S - \text{cuerda } ab^{***}}{3}$. Fig. 1.

---

* *abd* = 1/4 ángulo *acb* subtendido por el arco. En la fig. 2 el ángulo último excede á 180°.

** *db* = cuerda *dib* ó la mitad de *adb* es = $\sqrt{\text{flecha}^2 + (\frac{1}{2}\ ab)^2}$. Figs. 1 y 2.

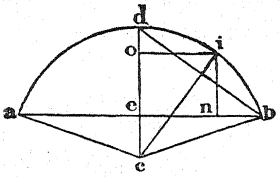

Fig. 1.

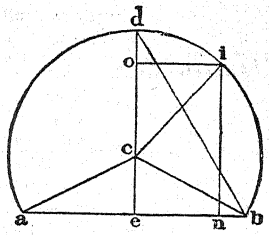

Fig. 2.

Las reglas para la figura 1 se aplican á todos los arcos iguales ó *menores* que una semicircunferencia.

Las reglas para la figura 2 se aplican á todos los arcos iguales ó *mayores* que una semicircunferencia.

**Radios** *ca, cd, ci* ó *cb*.

$$= \frac{(\frac{1}{2}\,ab)^2 + \text{flecha}^2}{2 \times \text{flecha}}. \text{ Figs. 1 y 2.}$$

$$= \frac{db^2\,\S}{2 \times \text{flecha}}. \text{ Figs. 1 y 2.}$$

$$= \frac{\frac{1}{2}\,ab}{\text{sen de } \frac{1}{2}\,acb}. \text{ Fig. 1 y 2.} \qquad = \frac{\frac{1}{2}\,db\,\S}{\text{sen } \frac{1}{2}\,bcd\,\|}. \text{ Figs. 1 y 2.}$$

$$= \frac{\text{flecha } de}{1 - \text{cos de } \frac{1}{2}\,acb}. \text{ Fig. 1.} \qquad = \frac{\text{flecha } de}{1 + \cos \frac{1}{2}\,acb\,\dagger}. \text{ Figs. 2.}$$

**Flecha ú ordenada en el centro** *de*.

$$= \text{radio} - \sqrt{\text{radio}^2 - (\tfrac{1}{2}\,ab)^2}. \text{ Fig. 1.}$$

$$= \text{radio} + \sqrt{\text{radio}^2 - (\tfrac{1}{2}\,ab)^2}. \text{ Fig. 2.}$$

$$= \text{radio} \times (1 - \cos bcd\,\|\,). \text{ Fig. 1.}$$

$$= \text{radio} \times (1 + \cos bcd\,\|\,)\dagger. \text{ Fig. 2.}$$

$$= \frac{db^2\,\S}{2 \times \text{radio}}. \text{ Figs. 1 y 2.}$$

$$= \tfrac{1}{2}\,ab \times \text{tang } abd\,(*). \text{ Figs. 1 y 2.}$$

$$= \text{aproximadamente } \frac{(\frac{1}{2}\,ab)^2}{2 \times \text{radio}}. \text{ Fig. 1.}$$

Cuando el radio es=cuerda *ab* el resultado es 6.7 por ciento más pequeño
Cuando es=3 × cuerda *ab* el resultado es 0.7 por ciento más pequeño.

**Ordenada lateral** como *ni*.

$$= \sqrt{\text{radio}^2 - en^2} + \text{flecha} - \text{radio. Figs. 1 y 2.}$$

$$= \text{aproximadamente } \frac{an \times nb}{2 \times \text{radio}}. \text{ Fig. 1.}$$

---

(*) *abd* es = 1/4 del ángulo *acb* subtendido por el arco.

† En verdad que esto debería leerse 1 *menos* coseno; pero los cosenos de ángulos entre 90° y 270° deben entonces ser considerados como negativos. Nuestra regla por tanto nos conduce al mismo resultado.

§ *db* = cuerda de *dib* ó la mitad de *adb* es = $\sqrt{\text{flecha}^2 + (\frac{1}{2}\,ab)^2}$. Figs. 1 y 2.

‖ *bcd* = la mitad del ángulo *acb* subtendido por el arco. En la figura 2 el último ángulo excede de 180°.

### Ángulo *acb* subtendido por el arco *adb*.

Un ángulo y su suplemento (como *bce* y *bcd*, fig. 2) tienen el mismo seno, el mismo coseno y la misma tangente.

**Advertencia.** Los senos, etc., siguientes son sólo de la mitad de *acb*.

$$\text{sen } \tfrac{1}{2}\, acb = \frac{\tfrac{1}{2}\, ab}{\text{radio}}. \text{ Figs. 1 y 2.}$$

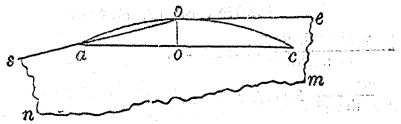
$$\cos \tfrac{1}{2}\, acb = \frac{\text{radio} - \text{flecha}}{\text{radio}}. \text{ Fig. 1;} \qquad = \frac{\text{flecha} - \text{radio}}{\text{radio}}. \text{ Fig. 2.}$$

$$\text{tang } \tfrac{1}{2}\, acb = \frac{\tfrac{1}{2}\, ab}{\text{radio} - \text{flecha}}. \text{ Fig. 1;} \qquad = \frac{\tfrac{1}{2}\, ab}{\text{flecha} - \text{radio}}. \text{ Fig. 2.}$$

$$\text{seno verso } \tfrac{1}{2}\, acb = \frac{\text{flecha}}{\text{radio}}. \text{ Figs. 1 y 2.}$$

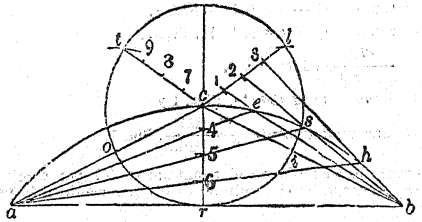
### Describir el arco de un círculo demasiado grande.

**Método 1.°** Sea *ac* la cuerda y *ob* la flecha del arco que se requiere. En una tira separada de papel *semn*, trácese *ac*, *ob*, *ab*, y también *be* paralela á la cuerda *ac*



será bueno hacer *bs*, *be*, un poco más largas que *ab*. Entonces córtese el papel cuidadosamente, á lo largo de las líneas *sb*, *be*, para que sólo quede la tira *sabemn*. Ahora, si los lados rectos *sb*, *be* se aplican al dibujo de modo que cualquier parte de ellos pase al mismo tiempo por los puntos *a* y *b* ó bien *b* y *c*, el punto *b* sobre la tira estará en la circunferencia del arco y se marcará con un punto. Así pueden encontrarse muchos puntos sobre el arco y unirse después para formar la curva.

**Método 2.°** Trácense la cuerda del arco *ab*, la flecha *rc*, y *ac*, *bc*. Descríbase un círculo desde *c* con un radio *cr*. Háganse cada uno de los arcos *ot*, *il*, iguales á *ro* ó *ri*, y trácese *st*, *cl*. Divídanse *ct*, *cl*, *cr*, en la mitad del número de partes



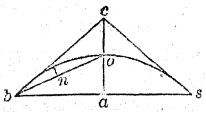
iguales en que se quiera dividir la curva. Trácense las líneas *b* 1, *b* 2, *a* 4, *a* 5, *a* 6, prolongadas hasta que se corten en *e*, *s*, *h*. Entonces *e*, *s*, *h*, serán puntos de la curva; y para la otra mitad trácense líneas semejantes desde *a* hasta 7, 8, 9; y otras desde *b* hasta que se encuentren como antes. Trácese á la mano la curva, por los puntos así determinados.

**Advertencia.** Puede con frecuencia ser útil recordar que en cualquier arco *bos* que no exceda de 29°, ó de otro modo, cuya cuerda *bs* sea por lo menos **diez y seis veces** su flecha *ao;* ésta será aproximadamente la mitad de *ae* siendo *bc*, *sc*, tangentes al arco. † Y viceversa, si en arcos análogos á este

† Para arcos de 29° resultará el valor de *oc* así obtenido demasiado corto en $\frac{3}{100}$.

hacemos *oc* igual *ao; c* será aproximadamente el punto de encuentro de las tangentes *bc, sc* del arco. También **la ordenada media ó flecha *n* de la mitad del arco** *ob* ú *os* será aproximadamente $^1/_4$ de *ao* flecha del arco entero.

En verdad, esta última observación se aplica con bastante precisión en muchos



casos hasta si el arco es mayor de 45°, porque si en ese caso tomamos $^1/_4$ de *os* para valor de la flecha *n*, el error será sólo de $\frac{1}{103}$, en menos, y por tanto despreciable en algunos dibujos y muy útil para encontrar los puntos de una curva de radio muy grande para ser trazada con el compás de división. De la misma manera $^1/_4$ de *n* será la flecha para el arco *nb* ó *no* y asimismo de los demás. Más abajo se dá **una tabla para encontrar la flecha de un semiarco** con mayor exactitud.

## ARCOS CIRCULARES DE USO FRECUENTE

La quinta columna sirve para encontrar puntos y trazar arcos, según el principio dado arriba, cuando son demasiado grandes para el compás. Casi nunca será necesario usar más de las tres primeras decimales de la quinta columna y después que el arco se ha subdividido en partes menores de 35° las primeras dos decimales serán suficientes. Original.

Para **rectificación de arcos circulares**, véase pág. 192.

**Si el radio=1 milla,** 1° = 92.1534 pies = 28.491$^m$
1′ = 1.5859 — — = .479$^m$
1″ = 0256 — — = .0076$^m$

( *N. del T.*)

**Si el radio=1 kilómetro,** 1° = 17.453m
1′ = .291m
1″ = .0048m

**Desarrollo de los arcos circulares. Si el arco excede á una semicircunferencia.** Véase pág. 192.

Conociendo la cuerda y la altura del arco ó flecha, divídase la altura por la cuerda; búsquese en la columna de las alturas (tabla pag. 191) el número igual á este cociente. Tómese el número correspondiente en la columna de las longitudes y multipliquese este último número por la longitud de la cuerda dada. (*N. del T.* — Esta tabla sirve para cualquier unidad de medida que se use.)

| .400 | 1.38322 | .425 | 1.42764 | .450 | 1.47377 | .475 | 1.52152 | .500 | 1.57080 |

Si el arco A es mayor que la semicircunf, sea H=su altura, $a$=circunf del círculo — A, y $h$=altura del arco $a$=(semicuerda)$^2$ ÷ H. Encuéntrese $a$ por la tabla como se dijo. Entonces A=circunf — $a$.

### Rectificación de un arco circular*.

(a) Fig. A. **Para encontrar aproximadamente* la longitud de un arco** GBC. De un extremo C del arco tírese una tang CE al arco. (Véase pág. 179.) Proiónguese la cuerda GFC, hacia D, y hágase CD=FC=$^1/_2$ GFC. De D con un radio=DG, trácese el arco GE. Entonces CE=arco CBG * aproximadamente.

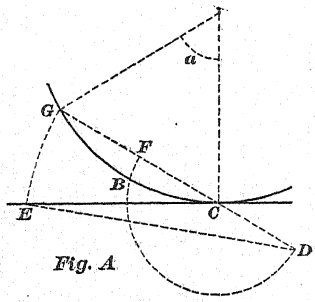

*Fig. A*

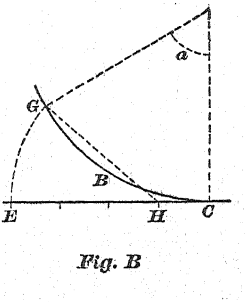

*Fig. B*

(b) Fig. B. En un círculo dado, **encontrar un arco** GC, aproximadamente * **igual á una recta** CE. Por el punto C en el círculo tírese una tang CE de la longitud dada. Hágase CH=$^1/_4$ CE. De H con radio=HE trácese arc EG. Entonces arco CBG=CE aproximadamente.

(c) En un círculo dado **trazar un arco igual en longitud á otro arco** de otro círculo: *primero* por (a) encuéntrese una línea recta igual al arco dado y por (b) búsquese el arco igual á esa línea recta.

**Para encontrar el desarrollo de un arco circular por medio de**

* El error crece con la 4.ª potencia del ángulo. En un arco de 60° es como de 4 minutos.

**la tabla siguiente.** Conociendo el radio del círculo y la medida del arco en grados, minutos, etc., se observará la siguiente :

**Regla.** Súmense las longitudes encontradas respectivamente frente á los grados, minutos, etc., del arco en la tabla y multiplíquese la suma por el radio del círculo.

Ej. : En un círculo de 12.23 m de radio hay un arco de 13 grados, 27 minutos y 8 segundos. ¿De qué tamaño es el arco?

Frente á 13 grados en la tabla encontramos .2268928
— á 27 minutos encontramos .0078540
— á 8 segundos encontramos .0000388
Suma= .2347856

Y .2347856 × 12.43 = 2.918385 m es la longitud que tiene el arco.

## Longitud de los arcos circulares para un radio 1.

*N. del T.* Esta tabla sirve para pies, metros ó cualquiera otra unidad que se use.

## SECTORES CIRCULARES, ANILLOS, SEGMENTOS, ETC.

**Área de un sector circular** *adbc*, fig. A.

$$= \frac{\text{arco } adb}{2} \times \text{radio } ca.$$

$$= \text{Area del círculo entero} \times \frac{\text{arco } adb \text{ en grados}}{360}.$$

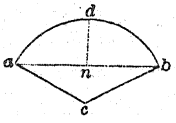

Fig. A.

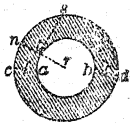

Fig. B.

**Área de un anillo circular**, fig. B.

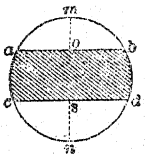
= Area del círculo mayor *cd* — área del menor *ab*.
= .7854 × (suma de diámetros *(cd + ab)* × (diferencia de los diámetros *cd* — *ab)*.
= 1.5708 × espesor *ca* × suma de diám *cd*, y *ab*.

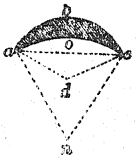
**Para encontrar el radio de un círculo que deba tener la misma área que un anillo circular dado** *csdab*, fig. B.

Trácese cualquier radio *nr* del círculo exterior y de donde dicho radio corte el círculo interior en *t* trácese *ts* perpendicular á él : *ts* es el radio que se busca.

**La anchura** *cd* = *bd*, fig. B.

= ½ diferencia de los diámetros *cd*, *ab*.
= ½ (diámetro *cd* — $\sqrt{1.2732}$ área del círculo *ab)*.





**Área de una zona circular** *abcd* = área del círculo *mn* — áreas de los segmentos *amb*, *cnd*. (Para áreas de segmentos véase más abajo.)

**Una luna circular** es una figura comprendida entre dos arcos *abc*, *aoc* de círculos de diferentes radios *ad*, *an* cuyas concavidades están de un mismo lado. Area de una luna circular *abco* = área del segmento *abc* — área del segmento *aoc*. (Para áreas de segmentos, véase abajo.)

Fig. C.

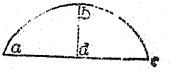


Fig. D.

**Para encontrar el área de un segmento circular** *abcd*, figs. C, D.

**El área del segmento** *adbn*, fig. A (al empezar la pág.), es :

= área del sector *adbc* — área del triángulo *abc*.
= ½ (arco *adb* × radio *ac* — *cn* × cuerda *ab)*.

**Teniendo el área de un segmento perteneciente á un círculo dado, encontrar su cuerda y flecha.**

Divídase el área por el cuadrado del diámetro del círculo, búsquese el cociente en la columna de las tablas siguientes, tómese de la tabla el número correspondiente en la columna de las flechas. Multiplíquese este número por el diámetro. El producto será la flecha que se busca y entonces la cuerda

$$= 2 \times \sqrt{(\text{diám} - \text{flecha}) \times \text{flecha}}.$$

**Tabla de áreas de segmentos circulares,** figs. C, D.

**Si el segmento excede á un semicírculo** su área es=área del círculo — área de un segmento cuya flecha es=(diámetro del círculo — flecha del segmento dado).

**El diámetro del círculo** es=(cuadrado de la mitad de la cuerda — flecha) ÷ flecha, sea que el segmento exceda al semicírculo ó no.

(*N. del T.* — Esta tabla sirve para cualquier unidad que se adopte : pies, metros, etc.)

| .352 | .246890 | .389 | .282618 | .426 | .318970 | .463 | .355733 | .500 | .392699 |

## ELIPSE (véase la pág. siguiente).

Distancia entre los focos $= fg = 2\sqrt{co^2 - bo^2}$; *

$$cf = gw = \frac{cw - fg}{2} = \frac{cw}{2} - \sqrt{co^2 - bo^2}.$$

* Porque $co = \frac{cw}{2} = \frac{fc + cg}{2} = \frac{fb + bg}{2} = fb.$

## LA ELIPSE

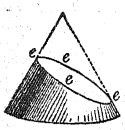

Fig. 1.

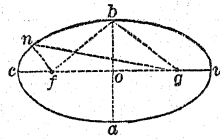

Fig. 2.

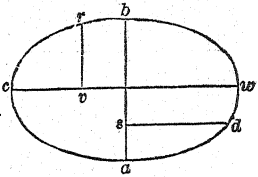

Fig. 3.

Una elipse es una curva *eeee*, fig. 1, formada por una sección oblicua hecha en un cono ó un cilindro sin cortar la base.

Tiene la propiedad de que, trazando dos líneas *nf*, *ng*, de cualquier punto *n* de su periferia á dos puntos especiales *f*, *g* de su eje mayor *c w* (llamados focos de la elipse) su suma será igual á la de otras dos líneas cualesquiera como *bf*, *bg* trazadas desde cualquier otro punto *b* de la periferia á los mismos focos *f*, *g* y además la suma de cualesquiera de dichas dos líneas será igual al eje mayor *cw*. La línea *cw* que divide la elipse en su mayor longitud en dos partes iguales se llama eje mayor; y la línea *ab* perpendicular al eje mayor que la divide igualmente en dos partes iguales se llama eje menor. Para encontrar la posición del foco de una elipse: desde cualquiera de los dos extremos *b* del eje menor mídanse las distancias *bf*, *bg*, fig. 2, cada una igual *oc*, ó la mitad del eje mayor.

El parámetro de una elipse es la longitud obtenida así: el eje mayor : al eje menor : : el eje menor: al parámetro. Cualesquiera línea *rv* ó *sd*, fig. 3, trazada desde la periferia y en ángulos rectos ó uno de los dos diámetros se llama ordenada; y las partes *cv*, *vw*, *bs*, *sa* de un diámetro entre la ordenada y la periferia se llaman abscisas.

**Para encontrar la longitud de cualquiera ordenada** *rv* ó *sd* **sobre cualquiera de los diámetros** *cw* ó *ba;* conociendo las abscisas *cv* ó *sa* y los dos diámetros *cw*, *ba;*

$$cw^2 : ba^2 :: cv \times vw : rv^2 \qquad ba^2 : cw^2 :: bs \times sa : sd^2$$

**Encontrar la periferia de una elipse.** Los matemáticos no les han dado á los hombres prácticos una regla simple para conseguir este objeto. Las llamadas fórmulas aproximadas no merecen este nombre. Son como siguen. Llamando D el eje mayor y *d* el menor:

$$\text{Regla 1. Periferia} = 3.1416\,\frac{D+d}{2}; \quad \text{Regla 2. } 3.1416\,\sqrt{\left(\frac{D^2+d^2}{2}\right)};$$

$$\text{Regla 3. } 2.2215\,\sqrt{D^2+d^2}.$$

Esta es la misma que la regla 2.ª pero con diferente forma.

$$\text{Regla 4. } 2\times\sqrt{D^2+1.4674\,d^2}.$$

En una elipse cuyos ejes sean 10 y 2, la periferia es muy aproximadamente 21: pero la fórmula 1.ª da para este caso=18.85, la fórmula 2.ª ó 3.ª=22.65 y la fórmula 4.ª=20.58. Si los diámetros son 10 y 6 la periferia realmente es = 25.59 y la fórmula 4.ª da 24.72. Estos ejemplos demuestran que ninguna de las fórmulas generalmente dadas son dignas de confianza. La siguiente fórmula del autor es suficientemente exacta para casos ordinarios y los errores que produce no llegan probablemente á más de una milésima. Cuando D no es más de 5 veces mayor que *d*.

$$\text{Periferia} = 3.1416\,\sqrt{\frac{D^2+d^2}{2}-\frac{(D-d)^2}{8.8}}.$$

**Si D es más de cinco veces** *d*, entonces en lugar de dividir $(D-d)^2$ por 8.8, divídase por el número que la corresponde en esta tabla.

| D ÷ *d* > | 5 = 6 | 7 | 8 | 9 | 10 | 12 | 14 | 16 | 18 | 20 | 25 | 30 | 40 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| *c* = | 8.8 | 9.0 | 9.2 | 9.3 | 9.35 | 9.4 | 9.5 | 9.6 | 9.68 | 9.75 | 9.80 | 9.87 | 9.92 | 9.98 |

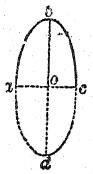
| D ÷ *d* = | 50 | 60 | 70 | 80 | 100 |
|---|---|---|---|---|---|
| *c* = | 10.04 | 10.10 | 10.17 | 10.23 | 10.35 |

La fórmula siguiente, original del señor Arnoldo Pears,

$$\text{Periferia} = 3.1416\,d + 2[(D - d) - \frac{d\,(D - d)}{\sqrt{(D + d) \times (D + 2d)}}.$$

**La tabla que sigue de arcos semielípticos** fué construída por nuestra fórmula.

Para usar esta tabla divídase la altura ó flecha del arco por su luz ó cuerda. El cociente será la altura de un arco cuya cuerda es 1. Búsquese este cociente en la



columna de las flechas ó alturas y tómese el número correspondiente en la columna de las longitudes, multiplíquese este número por la luz ó abertura real, el producto será la longitud que se busca. Cuando la altura viene á ser .500 de la cuerda (como al fin de la tabla), la elipse se transforma en un círculo. Cuando la altura excede de .500 de la cuerda, como en *abc*, tómese entonces *ao* ó la mitad de la cuerda como la elevación y divídase esta elevación por el eje mayor *bd* para buscar el cociente en la columna de alturas y multiplicarlo por el eje mayor, y obtenemos así la longitud del arco *bad* que es evidentemente igual á *abc*.

## TABLA DE LONGITUDES Ó DESARROLLOS DE SEMIARCOS ELÍPTICOS

(*N. del T.* — Esta tabla sirve para cualquier unidad que se elija: metros pies, etc.).

(Original.)

| Altura ÷ abertura | Longitud = abertura × por | Altura ÷ abertura | Longitud = abertura × por | Altura ÷ abertura | Longitud = abertura × por | Altura ÷ abertura | Longitud = abertura × por |

**El área de una elipse**=producto de los diámetros×.7854. Ej. : D=10; d=6.

Entonces 10×6×.7854=47.124. El área de una elipse es media proporcional entre las áreas de dos círculos descriptos sobre sus dos diámetros, por tanto puede encontrarse multiplicando las áreas de esos dos círculos y tomando la raíz cuadrada del producto. El área de una elipse es, por tanto, siempre mayor que la de la sección circular del cilindro de que se deriva la elipse.

**El diámetro de un círculo de la misma área que una elipse dada,**

$$\text{es} = \sqrt{\text{eje mayor} \times \text{eje menor}}.$$

**Para encontrar el área de un segmento elíptico cuya base es paralela á uno de los dos ejes.** Divídase la altura del segmento por el diámetro de que forma parte dicha altura ó flecha. De la tabla de segmentos circulares tómese el área opuesta al cociente y multipliquense entre sí, esta área, el eje mayor y el menor.

**Para trazar una elipse** teniendo sus ejes mayor y menor *ab*, *cd*, fig. 4.

Regla 1.ª De cualquiera de los dos extremos del diámetro corto, como *c*, trácense las distancias *cf*, *cf'*, cada una igual *ae*, es decir, á la mitad del eje mayor. Los puntos *ff* son los focos de la elipse. Prepárese una cuerda *fnf* ó bien *f'gf* con un lazo en cada extremo haciendo la longitud total de la cuerda, de extremo á extremo del lazo, igual al eje mayor. Colóquense alfileres en *f* y *f'* y colocando los lazos sobre

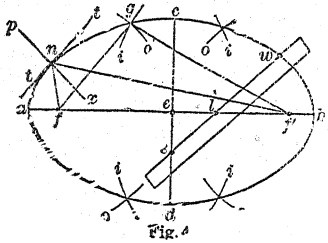

Fig. 4

ellos trácese la curva con un lápiz, el cual en cualquier posición *n* ó *g* mantenga la cuerda *fnf*, *f'gf* igualmente tensa.

Nota : Debido á la dificultad de mantener la cuerda igualmente estirada este método no es tan exacto como el siguiente :

Regla 2.ª En la orilla de una tira de papel *ws* márquese *wl* igual á la mitad del eje menor y *ws* igual á la mitad del eje mayor. Entonces en cualquier posición que se coloque esta tira, manteniendo el punto *l* sobre el eje mayor y el punto *s* sobre el eje menor, *w* marcará un punto en la periferia de la elipse y podremos obtener de este modo tantos puntos cuantos deseemos y trazar luego á mano la curva por sobre ellos.

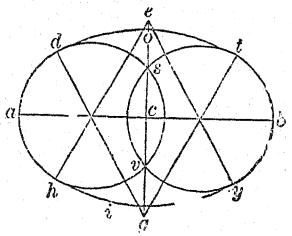
Regla 3.ª Desde los dos focos *f*, *f'*, fig. 4, con un radio igual á una parte cualquiera del diámetro mayor, descríbanse 4 arcos cortos *o*, *o*, *o*, *o*, y con un radio igual á la parte restante del diámetro mayor, descríbanse 4 arcos *i*, *i*, *i*, *i*. Las intersecciones de estos cuatro pares de arcos darán cuatro puntos de la periferia. De esta manera se puede encontrar cualquier número de puntos y trazar la curva **á mano.**

**Para trazar una tangente *tt* en cualquier punto *n* de una elipse** Trácese *nf*, *nf'*, á los focos; divídase el ángulo *fnf'* por medio de la línea *xp*, en partes iguales y trácese *tnt* perpendicular á *xp*.

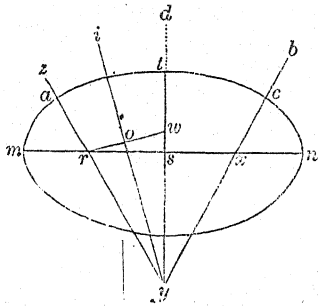
**Para trazar una normal *np* á un arco elíptico en cualquier punto *n* del arco.** Procédase como en la regla anterior para una tangente omitiendo sólo *á tt; np* será la normal.

**Para trazar un óvalo ó falsa elipse** cuando sólo se ha dado el diámetro mayor *ab*, úsese el siguiente método que dará curvas en las cuales la abertura *ab* no excederá en más de tres veces la flecha *co*. Sobre *ab* descríbanse dos círculos de cualquier radio que se intercepten; por sus intersecciones *sr* trácese *eg*, hágase *sg*, *ve*, cada una igual al diámetro de uno de los círculos. A través de los centros de los círculos trácense *ey*, *eh*, *gd*, *gt;* desde *e* descríbanse *hiy*, y desde *g* descríbase *dot*.

**Cuando se dan la abertura** *mn* **y la elevación** *st*. Háganse 2 distancias cua-



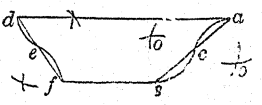
lesquiera *tw*, *mr*, iguales entre sí, pero ambas menores que *ts*. Trácese *rw* y por su centro *o* trácese la perpendicular *ioy*. Trácese *yrz*. Hágase *nx* igual *mr* y trácese *yxb*. Desde *x*, *r*, descríbanse *ne*, *ma*, y desde *y* descríbase *atc*. Haciendo *sd* igual *sy* obtenemos el centro para el otro lado del óvalo.



La belleza de la curva dependerá de la parte de *ts* que se toma para *mr* = *tw*. Cuando un óvalo es muy chato se necesitan más de tres centros para trazar una curva elegante; pero el encontrar estos centros da más trabajo que trazar una elipse.

**Sobre la línea dada** *as* **trazar el cimacio recto** *acs*. Búsquese el centro *c* de *as*.

Desde *a*, *c* y *s*, con la mitad de *as*, como radio, trácense los cuatro arcos *o*, *o*.



Las intersecciones *o*, *o*, son los centros para trazar el cimacio con dicho radio. Invirtiendo la posición de los arcos, obtendremos el *cimacio* inverso *def*.

## LA PARÁBOLA

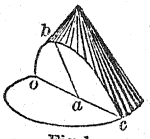


Fig. 1.

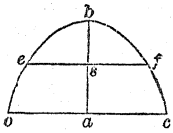

Fig. 2.

**La parábola común ó cónica** *obc*, es una curva formada por la sección de un cono en la dirección *ba* paralela á uno de sus lados. La misma línea curva *obe* se llama *perímetro* de la parábola; la línea *oc* es la *base*; *ba*, su altura ó eje; *b*, el vértice; una línea cualquiera *oa* ó *es*, fig. 2, tirada de la curva al eje perpendicular á éste es una *ordenada;* y las partes *sb*, *ab* del eje, entre la ordenada y el vértice *b*, son *abscisas*. El *foco* de una parábola es el punto del eje, en donde la abscisa *bs* es igual á la mitad de la ordenada *es*. La distancia del vértice al foco se llama *distancia focal*. La distancia al vértice se encuentra así: elévese al cuadrado cualquiera ordenada *oa;* divídase este cuadrado por la abscisa *ba* de esta ordenada y divídase el cociente por 4. La naturaleza de la parábola es tal que sus abscisas, *bs*, *ba*, etc., están entre sí como los cuadrados de sus respectivas ordenadas *es*, *oa*, etc.; esto es, $bs : ba :: es^2 : oa^2$; ó $bs : es^2 :: ba : oa^2$. Si se divide el cuadrado de cualquiera ordenada por su abscisa, el cociente será una cantidad constante, esto es, será igual al cuadrado de cualquiera otra ordenada dividida por su abscisa. Este cociente ó cantidad constante se llama *parámetro* de la parábola. Por tanto el parámetro se encuentra elevando al cuadrado á *es* ú *oa* (mitad de la base) y dividiendo dicho cuadrado por la altura *bs* ó *ba*, según el caso. Si se divide el cuadrado de cualquiera ordenada por el parámetro, el cociente será la abscisa de esa ordenada.

**Buscar el desarrollo de una curva parabólica.** La regla aproximada que dan varias carteras, es como sigue:

$$\text{Longitud} = 2 \times \sqrt{(\tfrac{1}{2}\ \text{base})^2 + 1\ \tfrac{1}{3}\ (\text{altura})^2}.$$

Cuando la altura no excede de $^1/_{10}$ de la base, esta fórmula puede considerarse en la práctica como exacta para usos ordinarios. Para altura $= {}^1/_3$ base da un error por exceso de ½ %; para altura = ½ base, como de $3\ {}^1/_3$ %; para altura = base como $8\ {}^1/_3$ %; $h = 2$ bases, como $12\ {}^1/_3$ %; $h = 10 \times$ base, ó más, como 15 ½ %.

**La regla que sigue dada por el autor es correcta**, para cualquier caso, con una aproximación de 1 en 800, y por tanto satisface á muchas aplicaciones.

Sea *adb*, fig. 3, ó *nad*, fig. 4, la parábola, en la cual se da la base *ab* ó *nd*, y la altura *cd* ó *ca*. Imaginemos trazada la figura completa *adbs* ó *nadb*, y en uno ú

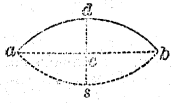

Fig. 3.

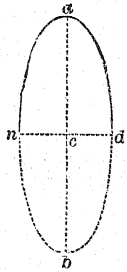

Fig. 4.

otro caso, supongamos su diámetro *mayor ab* la cuerda ó base, y la mitad del diámetro *cd*, la flecha de un arco de círculo. Búsquese la longitud de este arco de

círculo por medio de la regla y tabla dadas con este objeto. Luego divídase la cuerda ó base *ab* ó *nd* de la parábola por su altura *cd* ó *ca*. Búsquese el cociente en la columna base de la tabla que sigue y tómese de ella el correspondiente multiplicador. Multiplíquese por éste la longitud del arco de círculo, el producto será la longitud del arco *adb* ó *nad*, según el caso.

Para bases de parábolas menores de .05 de la altura ó diez veces mayores que aquélla, el multiplicador es muy aproximadamente 1, ó en otras palabras, la parábola será casi exactamente de la longitud del arco de círculo.

**Encontrar el área de una parábola** *manb*. Multiplíquese su base *mn*, fig. 5, por su altura *ab*, y tómense $^2/_3$ del producto.

El área de cualquier segmento, *ubv*, cuya base *uv* es paralela á *mn*, se encuentra de la misma manera, tomando *uv* y *sb* en lugar de *mn* y *ab*.

**Encontrar el área de una zona parabólica** *mnuv*. Regla 1.ª Búsquese

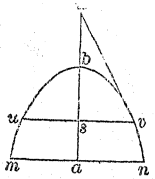

Fig. 5.

primero por la regla anterior el área de la parábola entera *mbn*, luego la del segmento *ubv;* y réstese la última de la primera.

Regla 2. Del cubo de *mn* réstese el cubo de *uv;* llámese *c* la diferencia. Del cuadrado de *mn*, réstese el cuadrado de *uv*, llámese *s* la diferencia; divídase *c* por *s*. Multiplíquese el cociente por $^2/_3$ de la altura *as*.

**Tabla de la longitud de las curvas parabólicas.** (Original.)

**Trazar una parábola** *cos* de base *cs* y altura *eo*, fig. 6. Hágase *ot* igual á la altura *eo*. Trácense *tc* y *st*, divídanse cada una de ellas en un número cualquiera de partes iguales, y numérense como en la figura. Unanse 1.1; 2.2; 3.3; etc.; luego trácese la curva á mano. Se observará que las intersecciones de las líneas 1.1; 2.2; etc., no dan punto de curva; pero una parte de cada una de aquellas líneas forma una tangente á la curva. Aumentando el número de divisiones de *ct* y *st*, se

forma una curva casi perfecta, que apenas se necesita corregirla á la mano. En la práctica es mejor dibujar primero la parte central de las dos líneas que se cortan en *o*, y de aquí seguir hacia abajo, trazando efectivamente sólo aquella parte de cada línea inferior sucesiva que sea necesaria para indicar la curva.

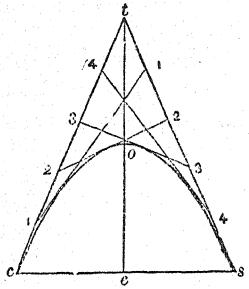

Fig. 6.

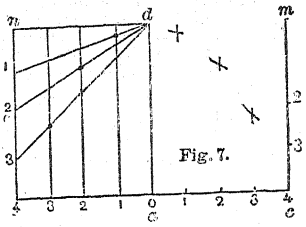

Fig. 7.

**También puede trazarse la parábola como sigue** : Sea *bc*, fig. 7, la base, y *ad* la altura.

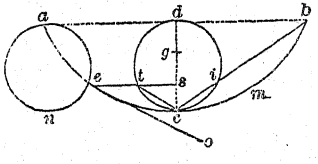
Trácese el rectángulo *bnmc;* divídase cada mitad de la base en cualquier número de partes iguales y numérense del centro hacia ambos lados. Divídase *nb*, mc en el mismo número de partes iguales; y numérense de arriba hacia abajo. Desde los puntos de división de la línea *bc* trácense líneas verticales y desde los puntos de los lados tírense líneas al punto *d*. Las intersecciones de las líneas 1.1, 2.2, etc., serán puntos de la parábola. Como en el caso anterior, no es necesario trazar las líneas enteras, sino simplemente porciones de ellas, como se indica entre *d* y *c*.

También puede trazarse una parábola dividiendo primero la altura *ab*, fig. 5, en cualquier número de partes, iguales ó desiguales, y luego calcular las ordenadas *us*, etc.; así : altura *ab* : cuadrado de la semibase *am* : : cualquiera abscisa *bs* : cuadrado de su ordenada *us*.

*Observación.* Cuando la altura de una parábola no es mayor de $^1/_{10}$ de su base, la curva coincide tan próximamente con un arco de círculo, que en la preparación de los dibujos de puentes de suspensión puede emplearse el arco de círculo si no se necesita gran precisión. También puede usarse el círculo aun cuando la altura llegue á un octavo de la base.

**Trazar una tangente** *wv*, **fig. 5, á una parábola desde un punto cualquiera** *v*. Trácese *vs* perpendicular al eje *ab*, prolónguese *ab* hasta que *bw* sea igual *sb*. Unase *wv*.

**La cicloide** *acb* es la curva descripta por un punto *a* de la circunferencia de



un círculo *an* durante una revolución completa de éste á lo largo de una línea recta *ab*, que se llama base de la cicloide.

**El vértice** de la cicloide está en *c*.

**La base** *ab* = circunferencia del círculo generador *an*,
= diámetro *cd* del círculo generador $\times \pi = 3.1416 \times cd$.

**Eje ó altura** $cd = an$.

**Longitud** $acb = 4cd$.

**Área** *acbd*=3 veces el área del círculo generador

$$= \frac{3\ cd^2\pi}{4} = cd^2 \times {}^3/_4\,\pi = cd^2 \times 2.3562.$$

**Centro de gravedad de la superficie en** *g*; $cg = {}^7/_{12}\,cd$. Centro de gravedad de la curva (línea *acb*) está en el eje *cd*, en un punto *s* distante $^4/_3$ *cd* del punto *c*.

**Trazar una tangente** *eo*, desde un punto cualquiera *e* de una cicloide. Trácese *es* en ángulo recto al eje *cd*; sobre *cd* describase el círculo generador *dct*; únase *tc*; desde *e* trácese *eo* paralela á *tc*. **La curva de más rápido descenso** es la cicloide; de manera que un cuerpo podría caer de *b* á *c* por la curva *bmc* en menor tiempo que por el plano inclinado *bic*, ó por otra línea cualquiera.

## SÓLIDOS. CUERPOS REGULARES

**Poliedro regular** es el que tiene todos sus lados y ángulos sólidos iguales. Sólo hay cinco, á saber :

| Nombre | Limitados por | Superficie (= suma de las superficies de todas las caras). Multip. por el cuadrado de la longitud de una arista por | Volumen = cubo de la longitud de una arista ó lado por |
|---|---|---|---|
| Tetraedro..... | 4 triángulos equiláteros. | 1.7320 | .1178 |
| Exaedro ó cubo. | 6 cuadrados. | 6. | 1. |
| Octaedro..... | 8 triángulos equiláteros. | 3.4641 | .4714 |
| Dodecaedro..... | 12 pentágonos equiláteros. | 20.6458 | 7.6631 |

**Teorema de Guldinus.** Para encontrar el **volumen de cualquier cuerpo** (como la masa irregular *abcm*, fig. A, ó el anillo *abcm*, fig. B), engendrado

Fig. A.

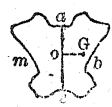

Fig. B.

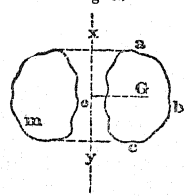

por una revolución completa ó parcial de una figura cualquiera (*abca*) alrededor de uno de sus lados (*ac*, fig. A), ó alrededor de un eje cualquiera *xy*, fig. B.

**Volumen** = superficie *abca* × longitud del arco descripto por su centro de gravedad G.

Si la revolución es completa, el arco descripto es=circunferencia=radio 0 G *× $2\pi$=radio 0 G *×6.283186; y *Volumen*=superficie *abca*×radio 0 G *×6.283186.

Si la revolución es incompleta,

$$\text{Revolución completa} : \text{Revolución incompleta} = \text{Circunferencia hallada arriba} : \text{Arco descripto}$$

(*) Medido perpendicularmente al eje de revolución.

## PARALELEPÍPEDOS

Fig. 1.

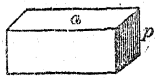

Fig. 2.

Fig. 3

Fig. 4.

Paralelepípedo es un sólido limitado por seis paralelogramos y de caras opuestas paralelas. Sólo mencionamos cuatro, á saber : el *cubo*, fig. 1, cuyas caras son cuadrados iguales y sus ángulos rectos; el *paralelepípedo rectángulo*, fig. 2, que tiene todos sus ángulos rectos y sólo las caras opuestas iguales; el *romboedro*, fig. 3, cuyas caras son todas rombos iguales; y el *prisma romboédrico*, fig. 4, cuyas caras son rombos, pero sólo iguales entre sí las opuestas. Todos los paralelepípedos son prismas.

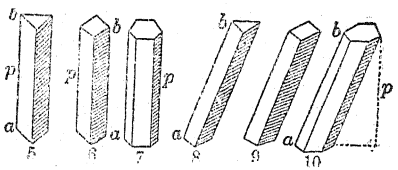
(*N. del T.* — Nos han parecido más sencillas estas definiciones.)

**Volumen de un paralelepípedo**=área de cualquier cara $a$ × distancia $p$ á la cara opuesta.

**Volumen de un cubo**=cubo de la longitud de un lado.
=1.90985 × volumen de la esfera inscrita.
=1.27324 × — de cilindro. inscrito
=3.81972 × — de cono. inscrito

**Diagonal de un cubo**=diámetro de la esfera circunscrita.
=1.7320508 × longitud de un lado del cubo.

## PRISMAS



Un prisma es un sólido de *bases* paralelas é iguales, cuyas caras laterales son paralelogramos, figs. 5 á 10.

Por tanto, los paralelepípedos precedentes son prismas. Prisma *recto* es aquel que tiene las caras perpendiculares á sus bases, figs. 5, 6 y 7, de no ser así, es *oblicuo*, figs. 8, 9 y 10. Si los polígonos de las bases son polígonos regulares, se dice que el prisma es *regular*, de cualquier otro modo es *irregular*.

**Volumen de un prisma cualquiera** (regular ó irregular, recto ú oblicuo) =área de una de sus bases × su altura $p$=área de la sección transversal perpendicular á las caras × longitud $ab$, figs. 5 á 10=3 × volumen de la pirámide de base y altura iguales á las del prisma.

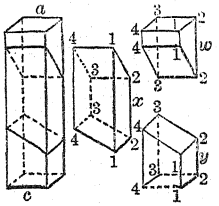
**Encontrar el volumen de un tronco de prisma**, cuya sección transversal perpendicular á sus caras puede ser triángulo, ó paralelogramo, ó un cuadrado (como en la fig. 10[1]/.), ó un polígono regular de cualquier número de lados, y cualquiera que sea la inclinación de una de las bases del tronco con respecto á la otra, sea una de ellas ó ninguna paralela á la base del prisma original.

$$\text{Volumen del tronco} = \frac{\text{Suma de las longitudes de las aristas paralelas}}{\text{número de dichas aristas (4 en la fig. } 10^1/_4)} \times \text{área de la sección transversa } \textit{perpendicular} \text{ á dichas aristas}$$

Esta regla puede aplicarse para calcular de antemano la cantidad de tierra que se ha de extraer de una excavación. Primero se divide con estacas, en cuadrados,

la superficie irregular del terreno. (Al medir los lados debe colocarse la cinta perfectamente *horizontal.*)

Los cuadros deben ser de tal dimensión que sin diferencias apreciables puedan considerarse como superficies planas horizontales ó inclinadas. Determinada la profundidad del fondo horizontal de la fosa ó excavación, y encontrados los



Figs. $10^1/_4$.

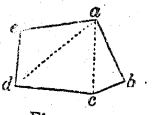


Fig. $10^1/_2$.

vértices de los cuadrados, determinamos la longitud de las cuatro aristas verticales paralelas de cada uno de los prismas truncados que resultan en la excavación. En la fig. $10^1/_4$ podemos representar por *y* uno de estos prismas truncados.

Si el prisma truncado es un tetraedro *irregular,* ó prisma poligonal, divídase primero en triángulos la sección transversal perpendicular á sus caras por medio de líneas tiradas desde uno cualquiera de sus ángulos, *a*, fig. $10^1/_2$. Calcúlese el área de cada uno de estos triángulos separadamente, luego considérese el prisma truncado entero formado de otros tantos prismas triangulares; calcúlese el volumen de cada uno de ellos por la regla precedente y súmese para obtener el volumen de todo el prisma truncado.

**Volumen de cualquier cilindro truncado.** Consideremos una cualquiera de sus bases y busquemos el área. Búsquese también el centro de gravedad *c* de la otra base y la distancia vertical *nc* de la base á dicho centro de gravedad.

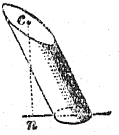

Fig. $10^3/_4$.

Tenemos **volumen del tronco** = área de la base × *nc* (fig. $10^3/_4$). La base inclinada *c* es una elipse. Su área es mayor que la de la base circular.

**Superficie de un prisma cualquiera,** figs. 5 á 10, recto ú oblicuo, regular ó irregular

$$= \left(\begin{array}{l}\text{perímetro de la sección}\\ \text{perpendicular á las caras}\end{array} \times \text{longitud } ab\right) + \begin{array}{l}\text{suma de las áreas}\\ \text{de las dos bases.}\end{array}$$

## CILINDROS

Cilindro es un sólido de bases paralelas, semejantes y limitadas por líneas de igual curvatura, cuyas secciones, pararelas á las bases, son iguales á éstas. De aquí que hayan cilindros circulares, elípticos y otros muchos; pero cuando no se

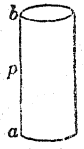

Fig. 11

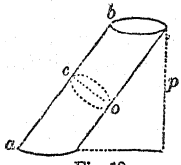

Fig. 12.

expresa á qué clase de cilindro nos referimos, se subentiende que se trata de cilindros circulares.

Cilindro *recto* es el que tiene las bases perpendiculares á sus lados, como en la fig. 11; de cualquiera otro modo es *oblicuo*, como en la fig. 12.

Si se cortan los extremos de un cilindro recto circular de manera que se transformen en oblicuas sus bases, se convierte aquél en cilindro elíptico; porque entonces ambas bases y todas las secciones á ellas paralelas son elipses.

Rara vez se presenta un cilindro circular oblicuo; puede concebírsele imaginando que las dos bases de la fig. 12 son círculos unidos por líneas rectas que forman la superficie lateral del cilindro.

Un cilindro es un prisma de infinito número de caras.

**Volumen de cualquier cilindro** (Circular, elíptico, etc., recto ú oblicuo).

=área de una de las bases × distancia *p* á la otra base

=área de la sección transversal medida perpendicularmente á las caras × longitud *ab*, figs. 11 y 12

=3 × volumen de un cono cuya base y altura sean iguales á las del cilindro.

**Superficie de un cilindro cualquiera** (Circular, elíptico, etc., recto ú oblicuo).

$$= \begin{pmatrix}\text{Circunferencia medida perpendicu-}\\ \text{larmente á los lados, como } co \text{ fig. 12}\end{pmatrix} \times \text{longitud } ab \Big) + \begin{matrix}\text{suma de las áreas}\\ \text{de las dos bases.}\end{matrix}$$

### Cilindro circular recto de altura=al diámetro.

| | |
|---|---|
| Volumen | =1 ½ volumen de la esfera inscrita. |
| Superficie curva | =superficie de la esfera inscrita. |
| Area de una de las bases | =$^1/_4$ de la superficie de la esfera inscrita=$^1/_4$ de la superficie curva. |
| Superficie entera | =1½ × superficie de la esfera inscrita=1½ × superficie curva. |

## UÑAS CIRCULARES CILÍNDRICAS

**I. Cuando el plano secante no corta la base.** Figs. 13 y 14.

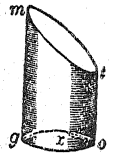

FIG. 13.

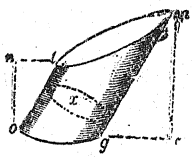

FIG. 14.

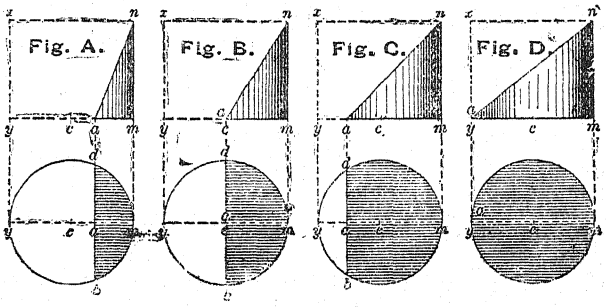
**Volumen de la uña** = área de la base $og \times \frac{1}{2}$ suma de las alturas *on*, *em*.
= área de la sección media *x* perpend á los lados $\times \frac{1}{2}$ suma de los lados *gm*, *ot*.

**Área de la superf curva** = circunf medida perp á los lados como en *x* $\times \frac{1}{2}$ suma de los lados *gm*, *ot*.

**Agréguense las supfs de los extremos** si se desea.

**Para las áreas de las secciones** perpendiculares á los lados, véase *Círculos*, y para las oblicuas, *La Elipse*.

**II. Cuando el plano secante toca la base.** Figs. A á D.



**Volumen** (recto ú oblicuo)

Fig. **A** $= (\frac{2}{3}\ ab^3 - ac \times$ área *admb* de la base$)\ \frac{mn}{am}$.

Fig. **B** $= \frac{2}{3}\ cb^2 \times mn$.

Fig. **C** $= (\frac{2}{3}\ ab^3 + ac \times$ área *admb* de la base$)\ \frac{mn}{am}$.

Fig. **D** $= \frac{1}{2}$ área del círculo $ym \times mn$.
$= \frac{1}{2}$ volumen del cilindro *xymn*.

**Superficie curva.** (uña *recta* solamente)

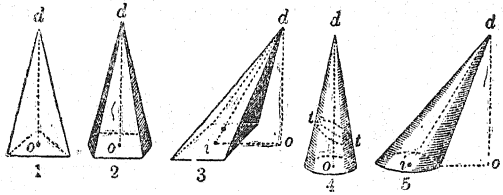
Fig. **A** $= (ab \times my - ac \times$ longitud arco *dmb*$)\ \frac{mn}{am}$.

Fig. **B** $= my \times mn$.

Fig. **C** $= (ab \times my + ac \times$ longitud arco *dmb*$)\ \frac{mn}{am}$.

Fig. **D** $= \frac{1}{2}$ circunf. de la base $my \times mn$.
$= \frac{1}{2}$ superf curva del cilindro *xymn*.

## PIRÁMIDES Y CONOS



**Una pirámide**, figs. 1, 2, 3, es un sólido que tiene por base una figura plana de cualquier número de lados, y por caras, triángulos que terminan todos en un punto, *d*, llamado *vértice*. Cuando la base es un polígono *regular*, la pirámide es regular; si no, es *irregular*.

**Un cono**, figs. 4 y 5, es un sólido cuya base es un plano de perímetro curvilíneo, y que se puede considerar engendrado por una línea recta, que apoya uno de sus extremos en un punto fijo *d*, que se llama el vértice, mientras el otro se mueve sobre el perímetro de la base. También se puede considerar el cono como una pirámide de infinito número de lados.

El eje de una pirámide ó cono, es la línea recta, *do*, en las figs. 1, 2, 4; y, *di* en las figs. 3 y 5, que une el vértice, *d*, con el centro de gravedad de la base Cuando el eje es perpendicular á la base, como en las figs. 1, 2, 4, se dice que la pirámide ó el cono, son *rectos;* cuando no, son *oblicuos*. Cuando se dice sólo *el cono* se entiende el *recto*. Si se corta un cono recto, con un plano *tt*, fig. 4, inclinado á la base, la nueva base, *tt*, es una *elipse* y el cono nuevo, *dtt*, es un cono *elíptico*.

**Volumen de la pirámide ó del cono**, regular ó irregular, recto ú oblicuo.

**Volumen** $= {}^1/_3$ del área de la base × la altura perpendicular *h*, ó bien *do*, figs. 1 á 5.

$= {}^1/_3$ del volumen del prisma ó cilindro que tienen la misma área en la base y la misma altura.

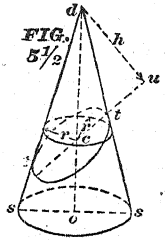
$= {}^1/_2$ del volumen del hemisferio de la misma base y altura.

O bien los volúmenes de un cono, un hemisferio y un cilindro, de la misma base y altura, están como 1, 2, 3.

**Área de las caras**, de la pirámide, recta, regular y del cono circular recto.

**Área** = semicircunf de la base × el lado*
En el cono esto equivale á
**Área** $= \dfrac{\text{área de la base}}{\text{radio de la base}} \times$ lado.

} Si se requiere agréguese el área de la base.



**Área de la superf del cono elíptico oblicuo**, *dtt*, fig. 5½; cortado de un cono circular recto *dss*. Del punto *c* donde el eje *do* del cono circular recto

* En la pirámide el lado se mide por la perpendicular bajada desde el vértice á uno de los lados del polígono de la base.

corta la base elíptica, *tt*, mídase una perpendicular, *r*, en cualquiera dirección, á la superf curva del cono. Sea, *v*=el volumen del cono oblicuo, *dtt;* sea *a*=área de su base elíptica, *tt*, y *h* la altura, *du*, medida perpendicularmente á dicha base. Entonces

$$\textbf{La superf curva} = \frac{ah}{r} = \frac{3v}{r}.$$

Si se requiere, agréguese el área de la base.

No se ha encontrado ninguna medida para la superficie del **cono circular oblicuo.**

**El área de la superficie de una pirámide irregular** recta ú oblicua = la suma de las áreas de las caras, medida cada una como un triángulo. Si se requiere, agréguese el área de la base.

## TRONCOS DE PIRÁMIDES Y CONOS

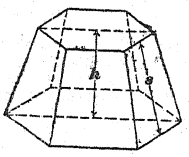


Fig. 6.

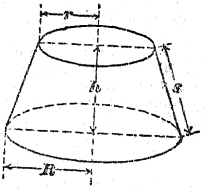

Fig. 7.

*a*=área de la base superior; *c*=circunf base sup.
A= — de la base; *C*= — inf.
M= — de la sección media paralela á las bases;
*h*=altura del tronco; *s*=lado del tronco *.

**En la fig. 7.**

*r*=radio de la base superior; R=radio de la base inf.

### Volúmenes.

**Tronco de pirámide** (fig. 6) **ó de cono** (fig. 7), regular ó irregular, recto ú oblicuo, de bases paralelas.

$$\textbf{Volumen} = \frac{h}{3}(a+\mathrm{A}+\sqrt{a\mathrm{A}}) = \frac{h}{6}(a+\mathrm{A}+4\mathrm{M}).$$

**Tronco de cono circular recto ú oblicuo.** Fig. 7.

$$\textbf{Volumen} = \frac{h}{3}\pi\,(r^2+\mathrm{R}^2+r\mathrm{R});\quad \pi = 3.1416.$$

**Área de las caras.** (Si se requiere, agréguense las bases.)

**Tronco de pirámide ó cono, recto, regular,**
de bases paralelas. Figs. 6 y 7.

$$\textbf{Área} = \frac{s}{2}(c+\mathrm{C})\ *.$$

**Para el tronco de cono recto** circular :

$$\textbf{Área} = \pi s\,(r+\mathrm{R});*\quad \pi = 3.1416.$$

**Tronco de pirámide irregular ú oblicua :**

**Área** = suma de las superficies de las caras.

Cada lado debe tratarse como un cuadrilátero. **Agréguense las áreas de las bases, si se desea.**

---

* En el tronco de pirámide, fig. 6, *s*, debe medirse á lo largo de la mitad de una de las caras, no sobre las aristas.

## PRISMOIDES

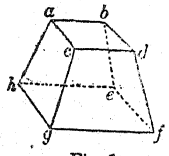

Fig. 1.

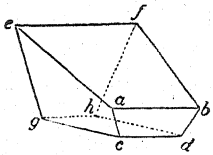

Fig. 2.

**Un prismoide** se define á veces como un sólido que tiene por bases dos figuras planas, unidas por superficies, en las cuales puede trazarse una línea recta entre sus lados paralelos. Estas figuras planas pueden ser paralelogramos ó no, y también pueden ó no ser paralelas entre sí.

Esta definición puede comprender al cubo ó cualquier otro paralelepípedo; el prisma; el cilindro (considerado como un prisma de infinito número de caras); la pirámide y el cono (en que una de las bases, la que forma el vértice, se considera infinitamente pequeña) y sus troncos de bases paralelas, y la cuña.

Pero el término prismoide, se restringe frecuentemente, al sólido de seis caras, cuyas bases paralelas son cuadriláteros desiguales y las caras laterales, trapezoides, como en las figs. 1 y 2, y, por algunos escritores, al caso en que las bases son *rectángulos*.

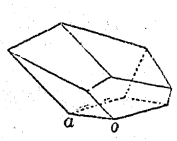
La **fórmula prismoidal** que vamos á dar se aplica á todos los sólidos que siguen y á otros como lo indicamos después.

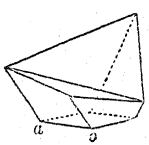
Sean A y *a*, las áreas de las bases paralelas;
M, una sección media paralela á ellas;
L, la distancia perpendicular entre las bases.

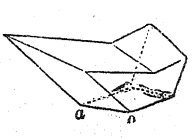
Entonces : $$\textbf{Volumen} = L \times \frac{A+a+4M}{6}$$

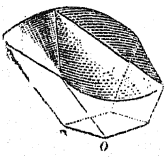
$$= L \times \text{área de la sección media.}$$

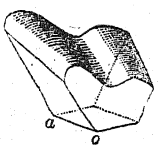
Las seis figuras que siguen representan algunos de los sólidos, comprendidos en la amplia definición que hemos dado del **prismoide** y á los que se aplica la fórmula. Deben considerarse como partes de una cortada en los trabajos de ferrocarriles, siendo *ao* la distancia horizontal entre las dos caras verticales y paralelas.

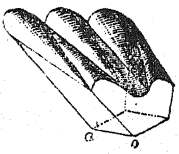






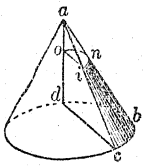


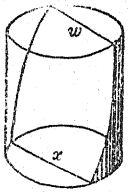




**La fórmula prismoidal se aplica también** á la esfera, hemisferio y otros segmentos esféricos; también á cualquier sección, como *abcd; onidbc*, del cono, en que los lados *ad*, *ac*, ó bien, *od*, *ic*, son *rectos;* como lo son solamente cuando el plano secante, *adc*, pasa por el vértice *a*. También al cilindro, cuando

el plano, *paralelo á los lados*, corta las bases, pero no, si como él, *wx*, es *oblicuo* (véase la figura). **En este último caso** se prolonga el plano hasta que corte los lados del cilindro y se mide el volumen de la *uña* así formada. Si se quiere





medir el tronco de uña, *wx*, se mide el vol de la pequeña uña que está sobre *w* y se resta de la grande.

Esta fórmula prismoidal, tan extensa y aplicable, fué encontrada por primera vez por Ellwood Morris, Ing. C. de Filadelfia, 1840.

## CUÑAS

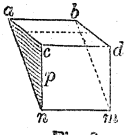


Fig. 8.

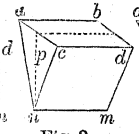

Fig. 9.

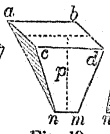

Fig. 10.

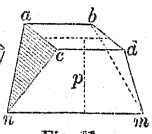

Fig. 11.

Se las define generalmente como un sólido engendrado, figs. 8 y 9, por un triángulo plano, *anc*, que se mueve, paralelamente á sí mismo, en línea recta. Esta definición requiere que los dos extremos triangulares de la cuña sean paralelos; pero una cuña puede tener la forma de las figs. 10 ú 11. Proponemos la siguiente definición que comprende todos los casos. Un sólido de cinco caras planas; una de las cuales es un paralelogramo, *abcd;* dos de cuyos lados, como *ac, bd*, están unidos por dos caras triangulares *acn, bdm*, á una arista ó línea *nm*, paralela á los otros lados opuestos *ab, cd*. El paralelogramo, *abcd*, puede ser rectángulo ó no, y lo mismo las otras dos caras. La regla siguiente se aplica á todas las cuñas :

$$\textbf{Volumen} = \frac{1}{6} \times \begin{matrix}\text{suma longitud de}\\ \text{las 3 aristas}\\ ab + cd + nm\end{matrix} \times \begin{matrix}\text{altura perp de la}\\ \text{arista sobre la base}\end{matrix} \times \begin{matrix}\text{ancho de la base}\\ (abcd)\\ \text{medido perp á } ab\end{matrix}$$

## ESFERAS

**La esfera** es un sólido engendrado por la revolución de un semicírculo alrededor de su diámetro. Todos los puntos de la superficie de la esfera equidistan de uno interior llamado centro. Cualquier línea que una dos puntos de la superficie pasando por el centro, es un diámetro ó *eje* de la esfera. Cualquier círculo descripto en la superficie de la esfera que tenga por centro el de la esfera, es un círculo máximo. La esfera, á igualdad de superficie exterior, encierra mayor volumen que cualquier otro sólido. La intersección de un plano con la esfera es un círculo.

**Volumen** de la esfera :

$= \frac{4}{3}\ \pi\ \text{radio}^3 \qquad = 4.1888\ \text{radio}^3$

$= \frac{1}{6}\ \pi\ \text{diámetro}^3 \qquad = .5236\ \text{diám}^3$

$= \frac{1}{6}\ \frac{\text{circunferencia}^3}{\pi^2} \qquad = .01689\ \text{circunf}^3$

$= \frac{1}{6}$ diám × área superficie.

$= \frac{2}{3}$ diám × área del círc° máximo

$= \frac{2}{3}$ volumen del cilindro circunscripto

= .5236 volumen del cubo circunscripto.

**Área de la superficie** de la esfera :

$= 4\ \pi\ \text{radio}^2 \qquad = 12.5664\ \text{radio}^2$

$= \pi\ \text{diám}^2 \qquad = 3.1416\ \text{diám}^2$

$= \frac{\text{circunf}^2}{\pi} \qquad = .3183\ \text{circunf}^2$

= diám × circunf

= 4 × área círc° máximo

= superficie curva del cilindro circunscripto

$= \frac{6 \times \text{volumen}}{\text{diám}}$

**Radio** de la esfera :

$= \sqrt[3]{\frac{3}{4}\ \frac{\text{volumen}}{\pi}} \qquad = .62035\ \sqrt[3]{\text{volumen}}$

$= \sqrt{\frac{\text{área superf}}{4\pi}} \qquad = \sqrt{.07958 \times \text{área superf}}$

**Circunferencia** de la esfera :

$= \sqrt[3]{6\ \pi^2\ \text{volumen}} \qquad = \sqrt[3]{59.2176\ \text{volumen}}$

$= \sqrt{\pi\ \text{área superf}} \qquad = \sqrt{3.1416\ \text{área superf}}$

$= \frac{\text{área superf}}{\text{diámetro}}$

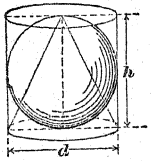
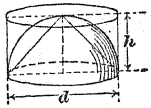
**Esfera, S; cono, C; y cilindro, Y;** de igual diámetro $d$ y de igual altura $h$. $(d = h)$.

$$\textbf{Volumen.}\quad Y = \frac{3}{2}S = 3C.$$

$$\textbf{Superficie curva.}\quad Y = S = \frac{2C}{\sqrt{1.25}}.$$





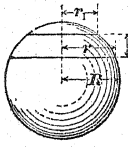
**Hemisferio, H; cono, C; y cilindro, Y;** de igual diámetro $d$, y de igual altura $h$. $(d = 2h)$.

$$\textbf{Volumen.}\quad Y = \frac{3}{2}H = 3C.$$

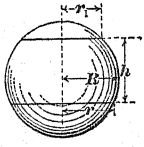
$$\textbf{Superficie curva.}\quad Y = H = C\sqrt{2}.$$

## Zonas esféricas y segmentos.

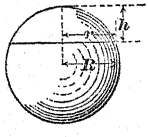
Sea R = radio de la esfera;
$r$ = radio de la base del segmento
= radio de cualquiera de las bases de la zona;
$r_1$ = radio de la otra base de la zona;
$h$ = altura de la zona ó segmento
$\pi = \frac{\text{circunf.}}{\text{diám.}} = 3.14159.$



Zona.



Zona.



Segmento.

Cáscara.

Entonces **Volumen de la zona** $= \frac{\pi}{2}\left(r^2 + r_1^2 + \frac{h^2}{3}\right)h.$

**Volumen del segmento** $= \frac{\pi}{2}\left(r^2 + \frac{h^2}{3}\right)h = \pi\left(R - \frac{h}{3}\right)h^2.$

**Superf curva de la zona ó segmento** $= \frac{h}{2R} \times$ superf de la esfera $= \frac{h}{2R} \times 4\pi R^2 = 2\pi Rh.$

En el segmento, $2R = \frac{r^2}{h} + h.$

## Cáscara esférica.

**Volumen** = volumen de la esfera $ab$ — volumen de la esf $cd$.

## Huso circular.

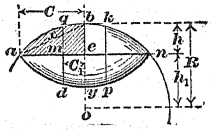
Es el sólido *abnya*, engendrado por la revolución de un segmento circular *abnea*, alrededor de su cuerda, *an*. Sea

$C = ae = \frac{1}{2}$ cuerda del segmento; $x = \sqrt{C^2 + h^2}$.
$h = eb =$ altura — = cuerda de la mitad del segmento;
$R = ob =$ radio del círculo. L = longitud del arco, *abn*;
$= \frac{C^2 + h^2}{2h}$; S = área *abe* $= \frac{LR}{4} - \frac{Ch_1}{2}$;
$h_1 = oe = R - h$ = distancia del centro, *o*, del círculo, al centro, *e*, de la cuerda.

Entonces **Volumen** $= 4\pi\left(\frac{C^2}{3} - Sh_1\right)$.

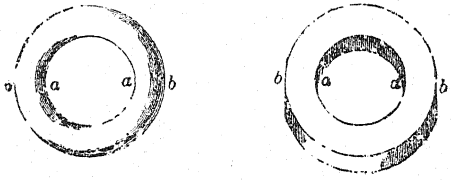
**Superf** $= 2\pi\ (2\ CR - Lh_1)$.

**Zona media** *qdkp*; $(C_1 = me)$.



$$\textbf{Volumen} = 2\pi\left[\left(C^2 - \frac{C_1^2}{3}\right)C_1 - h_1\ S_1\right], \text{ aquí } S_1 = \frac{\text{área, } qdkp}{2}.$$

## Anillo circular.



Sea
*a*=área de la sección *ab* del anillo;
*c*=circunf ó periferia de esta sección;
*d*=semisuma de los diámetros *aa* y *bb*.
$\pi$=3.141593.

Entonces **Volumen**$=\pi ad$; **Superficie**$=\pi cd$.

## Elipsoide ó esferoide.

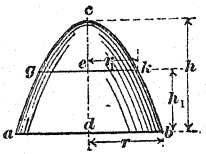
El elipsoide ó esferoide es el sólido engendrado por una elipse que gira alrededor de uno de sus diámetros. Si sobre su diám mayor resulta un esferoide *alargado*, si sobre el diám menor resulta *achatado*.

En ambos casos, **Volumen** $= \frac{\pi}{6} \times$ diámetro fijo $\times$ (diámetro de revolución)$^2$.

## Paraboloide.

Paraboloide es el sólido engendrado por la revolución de una parábola, *acb* alrededor de su eje, *cd*.

$r$=radio *db* de la base; $h$=altura *dc*.



**Paraboloide.**

$$\textbf{Volumen} = \frac{\pi r^2 h}{2} = \frac{h \times \text{área de la base}}{2};$$

$$\textbf{Superficie curva} = \left(\frac{2\pi r}{12\,h^2}\right)\left[(r^2 + 4h^2)^{\frac{3}{2}} - r^3\right].$$

## Tronco de paraboloide.

Extremos *gk* y *ab*, perpendiculares al eje *dc*. $r_1$=radio *ek* de la base *gk*. $h_1$=altura *de* del tronco.

$$\textbf{Volumen} = \text{paraboloide } acb - \text{paraboloide } gck = \frac{\pi}{2} h_1 \,(r^2 + r_1^2).$$

**Superficie curva**=superf *acb* — superf *gck*.

# PESO ESPECÍFICO

**1. El peso específico** ó **densidad relativa, D** *, de una substancia, es la relación entre el peso, W, de cualquier volumen de dicha substancia y el peso A del mismo volumen de otra substancia elegida como término de comparación. Por tanto : $D = \frac{W}{A}$.

**2.** Para los gases, el término de comparación es el aire seco á la temperatura de 0° Centígrado=32 Fahr, y á la presión barométrica de 760 mm=29.922 pulgadas.

**3.** Los sólidos y líquidos se comparan con el agua destilada en su máximum de densidad, á la temperatura de 4° C=39.2° F.

**4.** Para casi todos los propósitos del ingeniero, sirve cualquier agua fresca á cualquier temperatura ordinaria; con agua á 30° C=86° F, el error es de 4 por mil en exceso.

**5.** Cuando se sumerge un cuerpo en el agua, la fuerza de **empuje** ejercida por el agua sobre el cuerpo obra de abajo hacia arriba y le hace perder **una parte de su peso**, igual al peso del agua **desalojada** por el cuerpo; es decir, que si :

W=al peso del cuerpo en el aire,
$w$=su peso dentro del agua,
D=su peso específico,
A=al peso del agua desalojada;

entonces $A = W - w$; $D = \frac{W}{A} = \frac{W}{W - w}$.

**6.** Como el volumen V de un cuerpo de peso W, está en razón inversa de su densidad ó peso específico D, su densidad será igual también á la relación entre el volumen $V_s$ de la substancia elegida por término de comparación y el volumen $V_1$ de la substancia del cuerpo que pese lo mismo que aquélla; ó bien $D = \frac{V_s}{V_1}$.

**7.** El peso específico de las substancias más pesadas que el agua, se determina generalmente, pesando primero una masa de la substancia en el aire (W) y después pesándola completamente sumergida en el agua (obteniendo así su peso $w$ disminuído). Entonces (véase § **5**) $D = \frac{W}{W - w}$.

**8. Si el cuerpo pesa menos que el agua**, debe ser completamente sumergido, obrando contra su tendencia á flotar. Su peso $w$ en el agua, ó su tendencia á subir es entonces una cantidad *negativa* y debe idearse el modo de medirla; como, por ej., haciéndola obrar contra el platillo de la balanza hidrostática. Se tiene entonces, $A = W - (-w) = W + w$, es decir :

Pérdida debida á la inmersión=peso del cuerpo en el aire más su fuerza ascensional.

**9.** O bien : déjese primero flotar el cuerpo sobre el agua y anótese el desplazamiento del agua, por el nivel á que sube en un vaso angosto. Luego sumérjase todo el cuerpo y anótese también el desplazamiento V. Ahora el volumen $v$ desplazado por el cuerpo cuando flotaba, y V, volumen desplazado estando completamente sumergido, son proporcionales, respectivamente, al peso W del cuerpo y al peso $W - w$ de la masa de agua de volumen igual al del cuerpo. Así, $D = \frac{W}{W - w} = \frac{v}{V}$.

**10.** O bien átese al cuerpo liviano $b$, un cuerpo pesado, á manera de plomada ó lastre, S, de tal densidad y masa que ambos cuerpos se sumerjan en el agua. Sea W el peso del cuerpo liviano $b$ en el aire; Q el peso de ambos cuerpos en el aire y $q$ el de ambos también en el agua. Entonces $Q - q$ es el peso de una masa de agua de igual volumen que los dos cuerpos y $Q - W$=al peso S del cuerpo (que sirve de lastre) en el aire. Sumergiendo el lastre solo encuéntrese el peso $k$, del agua de igual volumen al del lastre, igual á la pérdida de peso del lastre debida á la inmersión. Entonces, para el peso A del agua igual en volumen a

* Estrictamente hablando, el «peso específico» se refiere al *peso* y la densidad relativa á la *masa;* pero como ambos son *numéricamente* iguales, se les considera indistintamente.

cuerpo liviano $b$ ó por la pérdida del peso de $b$ debida á la inmersión, se tiene $A = Q - q - k$; y para el peso específico D, del cuerpo liviano $b$, se tiene $D = \frac{W}{Q - q - k} = \frac{W}{W - w}$ en que $w$ es la fuerza ascensional desconocida de $b$, ó su peso *negativo* dentro del agua.

**11. Un cuerpo granular** ó **pulverulento** es una masa como el aserrín, la arena, el cemento, etc., ó un cuerpo poroso como un pedazo de madera, de concreto, etc., que tiene una parte sólida y otra parte de aire en sus intersticios. Así un pie cúbico de arena de cuarzo pesa como 100 lbs, mientras que un pie cúbico de piedra de cuarzo pesa como 160 lbs.

**12. El peso específico de las substancias porosas** se toma por el del compuesto de sólido y aire. Así una madera que pese (con su contenido de aire) 62.5 lbs por pie cúb, es decir, lo mismo que el agua, se dice que tiene un peso específico 1. Cuando á estos cuerpos hay que sumergirlos en agua para determinar su densidad se evita la absorción del agua por sus poros, dándole una ligera capa de barniz.

**13. La densidad de las substancias granulares** se establece algunas veces tomando la de la parte sólida que contienen. Así el cemento Portland ordinario, pesa (en el aire) de 75 á 90 lbs por pie cúb ó sea de 1.20 á 1.44 kilogramo por litro, es decir, que tiene por densidad de 1.20 á 1.44 (puesto que un litro de agua pesa *un kilogramo;* pero la parte sólida tiene una densidad de 3.00 á 3.25 y son estas cifras las que se toman generalmente para expresar su densidad.

**14.** Para determinar la densidad de las substancias (como el cemento) que **son solubles en el agua** ó afectadas por ésta, se pesan en líquidos (como la bencina, trementina, alcohol, etc.) que no los afecte, y el resultado que se obtenga se multiplica por la relación entre la densidad del líquido empleado y la del agua.

**15. La densidad de un líquido se determina** pesando iguales volúmenes del líquido y del agua.

**16.** O bien pésese en el líquido un cuerpo cuyo peso W en el aire y cuya densidad $d$ sean conocidos. Sea $w'$ su peso en el líquido. Entonces para la densidad D del líquido se tiene

$$W : W - w' = d : D; \text{ ó } D = \frac{d\ (W - w')}{W}.$$

**17.** O supongamos que el cuerpo **(16)** (que pesa W en el aire) pese $w$ en agua y que, como antes, pese $w'$ en el líquido en cuestión. Entonces, como la densidad del agua es=1, se tiene :

$$W - w : W - w' = 1 : D; \quad D = \frac{W - w'}{W - w}.$$

**18.** La densidad de los líquidos se determina generalmente observando la profundidad á que se sumerge en ellos un instrumento flotante llamado **aréometro.** Cuanto más se sumerge, menos denso es el líquido. En el **aréometro de Beaumé,** la profundidad de la inmersión está marcada en una escala arbitraria que tiene el aparato. Para líquidos más pesados que el agua el cero corresponde á la densidad 1 y 76° á la densidad 2. Para los más livianos, 10° corresponde á la densidad 1; y 60° á 0.745.

**19.** En el **aréometro de Twaddell** para líquidos más pesados que el agua,

$$\text{la densidad} = \frac{5 \times \text{N.° de grados} + 1{,}000}{1{,}000}.$$

Así, si la lectura es de 90°,

$$\text{la densidad} = \frac{5 \times 90 + 1{,}000}{1{,}000} = \frac{1{,}450}{1{,}000} = 1.45.$$

**20. En el aréometro de Nicolson,** muy usado también para sólidos, la densidad se deduce del peso requerido para hacerlo sumergir hasta un punto determinado fijo. Este aréometro consiste en un cuerpo metálico hueco, del que sube una varilla que sostiene un platillo que siempre queda sobre el agua. Del flotador hueco está suspendido abajo como lastre, otroplatillo pesado que siempre está sumergido como el flotador. En la varilla que sostiene el platillo superior está marcado el punto fijo, al que se obliga siempre en las experiencias á situarse al nivel del líquido. La densidad se determina por medio de los pesos en los dos platillos respectivamente.

**21.** La determinación de la **densidad de los gases** requiere la intervención y conocimientos de químicos expertos.

## Tabla de pesos específicos.

En esta tabla el peso específico del aire y el de los gases, están también comparados con el del agua en lugar de estarlo con el del aire. Así se usa últimamente.

| El peso específico de cualquier substancia es=**su peso en gramos por centímetro cúbico.** | Peso específico medio. |
|---|---|
| *N. del T.* — El peso de un litro (un decímetro cúbico) de cualquier substancia es un número *de kilogramos*=á su peso específico. | |
| Aire atmosférico á 60° Fahr (15°.6 C) y bajo la presión de una atmósfera pesa $^1/_{813}$ parte de lo que pesa el agua á 60°F = 15° .6.C | .00123 |
| Alcohol puro | .793 |
| — de comercio | .834 |
| — absoluto | .916 |
| Alabastro llamado así falsamente pero realmente mármol | 2.70 |
| — real..... término medio. | 2.31 |
| Aluminio | 2.6 |
| Antimonio fundido de 6.66 á 6.74..... término medio. | 6.70 |
| — nativo..... — — | 6.67 |
| Antracita. (Véase carbón abajo.) | |
| Asfalto de 1 á 1.8..... — — | 1.4 |
| Aceites: de ballena; de oliva..... — — | .92 |
| Aceite de trementina | .87 |
| Arena de cuarzo puro perfectamente seca y suelta | * |
| Si se la mueve ligeramente se compacta como de 2 á 3% y apisonada como 12% cuando está seca. | |
| Arena perfectamente húmeda, con intersticios llenos de agua | 1.89 á 2.06 |
| Arena angular, cuarzo puro con granos secos muy grandes y muy pequeños puede pesar | 1.87 |
| Si cualquiera arena ordinaria pura y natural se separa en dos ó tres ó más porciones de granos de diferentes tamaños, una medida de cualquiera de estas porciones pesará considerablemente menos que una medida igual de la arena original. Así una arena que pese (1.57 kilog el litro) puede dar otras que no pesen más que .98 á 1.20. A (1.57 kilog el litro) un volumen de cuarzo puro ha producido 1.68 de arena, en el cual el sólido ocupa .6; y el vacío .4. Pero si esta misma arena se compacta á 1.76 kilog el litro, entonces una medida de cuarzo sólido hace 1 $^1/_2$ medidas de arena, de la cual $^2/_3$ son sólidos y $^1/_3$ vacío. | |
| La arena conserva mucho la humedad y en grandes volúmenes rara vez está seca como se supone en esta tabla. Pero con su natural humedad y flojedad es más liviana que cuando está seca, no excediendo entonces el término medio de su peso de 1.36 á 1.44 kilog el litro. | |
| Areniscas propias para construcción, secas, 2.1 á 2.73 | 2.41 |
| — de cantera amontonadas. | |
| (Una medida sólida hace como 1 $^3/_4$ apiladas.) | |
| Arcilla esquistosa colorada ó negra 2.4 á 2.8..... término medio. | 2.6 |
| — — de cantera en pilas..... — — | 1.47 |
| Acero 7.7 á 7.9. El más pesado contiene menos carbón | 7.85 |
| El acero no es más pesado que el hierro del cual se hace; á menos que el hierro tenga impurezas que bote durante su conversión en acero. | |
| Abeto perfectamente seco (nota al pie de caoba española) | .4 |
| Mil pies (2.36 m cub), etc., pesan .930 toneladas (medida de tablas.). | |

* El peso específico de la arena pura de cuarzo, encontrado como se indicó al comenzar este capítulo de pesos específicos, es por supuesto el mismo que el del cuarzo puro (2.65); pero un volumen de arena seca pesa sólo de 1.44 á 1.7 veces más que igual cantidad de agua. La mayor parte de los autores dan 1.5 de peso específico.

## Tabla de pesos específicos.

| El peso específico de cualquier substancia es=**su peso en gramos por centímetro cúbico.** | Peso específico medio. |
|---|---|
| Alquitrán..... término medio. | 1. |
| Agua de lluvia pura ó destilada á 32° Fahr (0° C) barómetro á 760 mm..... | .9986 |
| Agua de lluvia pura ó destilada á 62° Fahr (16°7 C) barómetro á 760 mm..... | .99768 |
| Agua de lluvia pura ó destilada á 212° Fahr (100° C) barómetro á 760 mm..... | .955 |
| Agua de mar, 1.026 á 1.030..... término medio. Aun cuando se supone generalmente el peso del agua fresca como .998 kilog el litro, sin embargo .997 kilog el litro es más cercano á la verdad en temperaturas ordinarias como de 21° C. | 1.028 |
| Barro seco compacto..... | 1.28 á 1.76 |
| — húmedo comprimido medianamente..... | 1.76 á 2.08 |
| — — fluido..... | 1.66 á 1.92 |
| Basalto..... | 2.9 |
| Bismuto fundido. También nativo..... término medio. | 9.74 |
| Betún sólido. Véase asfalto. | |
| Bronce : cobre 8 partes; estaño 1 (metal de cañón) 8.4 á 8.6. término medio. | 8.5 |
| Boj seco..... — — | .96 |
| Calcita transparente..... | 2.722 |
| Cok de buen carbón (pedazos sueltos)..... | .37 á .51 |
| — un *bushel* colmado (*bushel*=36.34766 litros) 35 á 42 lib (15.87 á 19.05 kilog)..... | |
| Cok, 1 tonelada ocupa de 80 á 97 pies cúbicos (de 2.265 á 2.747 met. cúb.)..... término medio. Quemando el carbón aumenta en volumen de 25 á 50 por ciento. Igual peso de cok y carbón evaporan casi iguales pesos de agua y cada uno como el doble del mismo peso de madera seca. | |
| Corindón puro de 3.8 á 4..... | 3.9 |
| Cerezo perfectamente seco..... término medio. Mil pies corridos de tablas 12 por 1 pulgada pesa 1.562 toneladas. | .672 |
| Carbón antracita 1.3 á 1.7 generalmente ..... | 1.5 |
| — — en pedazos de cualquier tamaño. término medio. | .83 á .90 |
| — — — regulares..... | .90 á .96 |
| — — *bushel* colmado de 77 á 83 lib (más ó menos 1 kilog el litro)..... | |
| Un metro cúbico sólido tiene por término medio como 1.75 metros cúbicos cuando está en pedazos del tamaño que se acostumbra en el mercado. 1 tonelada en pedazos sueltos tiene más ó menos de 40 á 43 pies cúbicos (de 1,132 á 1,218 litros). A 54 lib por pie cúbico, una yarda cúbica pesa 1,458 lib=.651 toneladas. El metro cúbico pesa 824 kilogramos. | |
| Carbón bituminoso de 1.2 á 1.5..... | 1.35 |
| — — en pedazos de cualquier tamaño; sueltos..... | .75 á .83 |
| — — ligeramente quebrado..... | .82 á .90 |
| Carbón betuminoso un *bushel* (36,348 litros) colmado, suelto de 70 a 78 lib (de 32 á 35 kilog : más ó menos). | |
| Carbón betuminoso 1 tonelada ocupa de 43 á 48 pies cúbicos, es decir, de 1,271 á 1,359 litros. Un metro cúbico sólido tiene más ó menos 1.75 metros cúbicos partidos en pedazos sueltos como se usa para el mercado. | |
| Cemento hidráulico americano Rosendale en polvo suelto. tér. m°. | .90 |

## Tabla de pesos específicos *.

| El peso específico de cualquier substancia es=**su peso en gramos por centímetro cúbico.** | Peso específico medio. |
|---|---|
| Cemento hidráulico americano Louisville (en polvo)..... | .79 |
| — — inglés de Portland, (en polvo)..... | 1.30 á 1.63 |
| Cemento hidráulico inglés de Portland, un barril de 400 á 430 lib (de 181 á 195 kilog). | |
| Cemento hidráulico francés de Boulogne Portland..... | 1.22 á 1.41 |
| Ocurren á menudo diferencias de 40 á 50 kilog por tonelada más ó menos en el cemento de la misma fábrica, debido no solamente á la dificultad de medirlo con exactitud, sino á la falta de homogeneidad en la composición de la piedra, grado de calcinación, molida, sequedad, etc. | |
| Cobre fundido..... 8.6 á 8.8..... | 8.7 |
| — laminado..... 8.8 á 9.0..... | 8.9 |
| Cristal. Cuarzo puro. (Véase cuarzo.) | |
| Corcho..... | .25 |
| Cascajo casi lo mismo que arena. (Véase arena.) | |
| Cicuta perfectamente seca. (Véase nota en caoba española.)..... | .4 |
| Mil pies corridos de tabla de 12 pies 1 pulg pesa .930 toneladas. | |
| Caucho..... término medio. | .93 |
| Cal viva de piedra caliza ordinaria y mármol 1,470 á 1,570 kilog el metro cúbico..... | 1.50 |
| Cal viva en pequeños pedazos; ó molida, suelta, 800 á 900 kilogramos el metro cúbico..... | .85 |
| En cualquiera de los dos casos una medida sólida hace como 1.8 medida suelta; y entonces .555 de la masa es sólida y .445 vacíos. | |
| Para medir correctamente, ninguno de los pedazos debe exceder de $^1/_8$ ó $^1/_{10}$ de la más pequeña dimensión de los envases usados para medir. | |
| Cal viva molida suelta..... | .85 |
| — — — bien movida..... | 1.02 |
| — — — perfectamente triturada..... | 1.20 |
| Caoba española seca **..... término medio. | .85 |
| — de Honduras..... — — | .56 |
| Cuarzo ordinario puro 2.64 á 2.67..... | 2.65 |
| — — bien pulverizado..... | 1.50 |
| — — finamente pulverizado, bien empaquetado..... | 1.79 |
| — de cantera, suelto. Una medida sólida hace 1 $^3/_4$ en pedazos y apilados..... | 1.40 |
| Cera de abejas..... término medio. | .97 |
| Circón, 4.0 á 4.9..... | 4.45 |
| Diamante, generalmente 3.51 á 3.55..... | 3.53 |
| Diorita 2.8 á 3.2..... | 3. |
| — de canteras en montonces sueltos..... | 1.71 |
| Durazno..... | 1.15 |
| Eter..... | .716 |
| Ebano seco..... término medio | 1.22 |
| Esmeralda 2.63 á 2.76..... | 2.7 |
| Esteatita 2.65 á 2.8..... término medio. | 2.73 |
| Estaño fundido 7.2 á 7.5..... | 7.35 |
| Fresno, perfectamente seco. (Véase la nota puesta en la caoba española)..... | .752 |
| Mil pies corridos de tabla de 12 pulg por 1 pulg pesan 1,748 toneladas. | |

* *N. del T.* — Hemos tomado la lista de pesos específicos de la 16ª edición.

**Las *maderas verdes* pesan generalmente desde 1/5 hasta cerca de la mitad más que las secas; y las maderas ordinarias de construcción cuando están tolerablemente secas como 1/6 más que las perfectamente secas.

## Tabla de pesos específicos y pesos.

| El peso específico de cualquier substancia es=**su peso en gramos por centímetro cúbico.** | | | Peso específico medio. |
|---|---|---|---|
| Fresno blanco americano seco | | | .61 |
| Mil pies corridos de 12 × 1 pulgada pesan de 1,414 toneladas. | | | |
| Feldespato 2.5 á 2.8 | término medio. | | 2.65 |
| Gas ácido carbónico es 1 $^1/_2$ veces más pesado que el aire. | término medio. | | .00187 |
| Greda seca de alfarería 1.8 á 2.1 | — | — | 1.9 |
| — — en terrones | — | — | 1.008 |
| Grasa | — | — | .93 |
| Granate 3.5 á 4.3; precioso 4.1 á 4.3 | — | — | 4.2 |
| Granito 2.56 á 2.88. (Véase piedra caliza.) | | | 2.72 |
| Gneis ordinario 2.62 á 2.76 | término medio. | | 2.69 |
| — en pilas sueltas | — | — | 1.54 |
| Gutapercha | — | — | .98 |
| Guayaco seco | — | — | 1.33 |
| Gas nitrógeno es como $^1/_{35}$ partes más ligero que el aire | | | .0012 |
| Hornablenda negra 3.1 á 3.4 | término medio. | | 3.25 |
| Hidrógeno, es 14 ½ veces más liviano que el aire, y 16 veces más liviano que el oxígeno | término medio. | | .000084 |
| Hielo .917 á .922 | — | — | .92 |
| Hierro fundido 6.9 á 7.4 | — | — | 7.15 |
| — — supuesto generalmente á * | — | — | 7.21 |
| *Metal para cañones* | | | 7.48 |
| Hierro forjado 7.6 á 7.9; el más puro tiene el mayor peso específico | término medio. | | 7.77 |
| Hierro en grandes barras cilíndricas. | | | |
| — supuesto generalmente á | | | 7.6 |
| Hierro en láminas | término medio. | | 7.76 |
| El hierro liviano es señal de que está impuro. | | | |
| Ladrillo bien prensado | término medio. | | 2.40 |
| — duros ordinarios | — | — | 2.00 |
| — blando inferior | — | — | 1.60 |
| Latón (cobre y zinc) fundidos, 7.8 á 8.4 | — | — | 8.1 |
| Marfil | — | — | 1.82 |
| Manteca de puerco | — | — | .95 |
| Mármoles. (Véase piedra caliza). | | | |
| Mampostería de granito ó piedra caliza bien preparada | | | 2.64 |
| Mampostería de granito (bien desbastada ó emparejando las piedras de morrillos y teniendo como $^1/_3$ de la masa de mortero. | | | 2.46 |
| Mampostería de granito bien desbastado, piedra bruta seca | | | 2.21 |
| Mampostería de granito toscamente desbastado, de piedra bruta y con $^1/_4$ á $^1/_3$ de mortero | | | 2.40 |
| Mampostería de piedra arenosa; como $^1/_8$ parte menos que la anterior. | | | |
| Mampostería de ladrillo comprimido de juntas finas. | término medio. | | 2.24 |
| — — mediana calidad | | | 2.00 |
| — — ordinario; ladrillos inferiores blandos. | término medio. | | 1.60 |
| Mercurio á 32° Fahr=0° C | | | 13.62 |
| — 60° F=15° 6 C | | | 13.58 |
| — 212° F=100° C | | | 13.38 |
| Mica 2.75 á 3.1 | | | 2.93 |
| Mortero fraguado 1.4 á 1.9 | | | 1.65 |
| Nogal perfectamente seco | | | .66 |
| Nafta | | | .848 |
| Nieve, acabada de caer | | | .08 á .19 |
| — húmeda y compactada por la lluvia | | | .24 á .80 |

(*) Véanse las tablas del peso del hierro fundido más adelante.

## Tabla de pesos específicos y pesos.

| El peso específico de cualquier substancia es = **su peso en gramos por centímetro cúbico.** | Peso específico medio. |
|---|---|
| Nogal, negro perfectamente seco. (Véase nota en caoba española.) | .61 |
| Mil pies, etc. pesan 1,414 toneladas. | |
| Nogal de América perfectamente seco | .85 |
| Olmo perfectamente seco. (Véase la nota puesta en caoba española) término medio. | .56 |
| Mil pies corridos de tabla de 12 por 1 pulgada pesan 1.302 toneladas. | |
| **Oro** fundido puro, ó de 24 quilates | 19.258 |
| — nativo puro 19.3 á 19.34 término medio. | 19.32 |
| — que contiene plata frecuentemente 15.6 á 19.3. | |
| — puro forjado 19.4 á 19.6 | 19.5 |
| Oolitas 1.9 á 2.5 término medio. | 2.2 |
| Piedra de chispa — — | 2.6 |
| Plomo de comercio 11.30 á 11.47 en barras ó fundido | 11.38 |
| Piedra caliza y mármoles 2.4 á 2.86 | 2.6 |
| — — — ordinariamente como | 2.7 |
| Piedra caliza y mármoles de cantera en fragmentos irregulares: un metro cúbico sólido hace como 1.9 metros cúbicos perfectamente suelto; ó como 1 $^{3}/_{4}$ metros amontonados. En este último caso, .571 del montón es sólido, y las restantes .429 partes de él están vacías amontonado. | 1.54 |
| Petróleo | .878 |
| Pino blanco perfectamente seco .35 á .45 * | .40 |
| 1,000 pies ó 305 metros corridos de tablas de 12 por 1 pulgada pesan .930 toneladas *. | |
| Pino amarillo del Norte .48 á .62 | .55 |
| Mil pies corridos de tablas de 12 por 1 pulgada pesan 1.276 toneladas *. | |
| Pino amarillo del Sur 64 á 80 | .72 |
| Mil pies, etc , pesan 1.67 toneladas *. | |
| Pino de corazón, del amarillo, del Sur (verde). (Nota al pie de caoba española.) | 1.04 |
| Mil pies, etc., pesan 2.418 toneladas. | |
| Pólvora | 1.0 |
| Pórfido 2.66 á 2.8 | 2.73 |
| Platino 21 á 22 | 21.5 |
| — nativo en granos 16 á 19 | 17.5 |
| Pizarra 2.7 á 2.9 término medio. | 2.8 |
| Plata | 10.5 |
| Rubí y zafiro 3.8 á 4.0 | 3.9 |
| Resina | 1.1 |
| Roble fuerte perfectamente seco, .88 á 1.02 * término medio. | .95 |
| — blanco perfectamente seco, .66 á .88 | .77 |
| — rojo negro, etc. * término medio. | .51 á .72 |
| Sal ordinaria; Siracusa, Nueva York | .72 |
| — — Islas Turcas, Cádiz, Lisboa | .99 |
| — — San Barts | 1.12 |
| — — muy seca de las Indias Occidentales | 1.18 |
| — — Liverpool | .67 |
| — fina de Liverpool para uso de mesa e | .78 |
| Serpentina 2.5 á 2.65 | 2.6 |
| Sicomoro, perfectamente seco. (Véase nota al pied . caoba española.) | .59 |
| Mil pies, etc., pesan 1.376 toneladas. | |
| Sulfuro término medio. | 2. |
| Sebo — — | .94 |
| Tiza 2.2 á 2.8. (Véase piedra caliza de cantera.)... — — | 2.5 |

* Véase la nota ** pág. 225.

## Tabla de pesos específicos y pesos.

| El peso específico de cualquier substancia es = **su peso en gramos por centímetro cúbico.** | Peso específico medio. |
|---|---|
| Tierra común perfectamente seca y suelta | 1.15 á 1.28 |
| — — — — movida | 1.31 á 1.47 |
| Tierra común perfectamente seca moderadamente pisada | 1.44 á 1.60 |

# PESOS Y MEDIDAS

**Las medidas de longitud y peso de los Estados Unidos y de Inglaterra,** de la misma denominación, pueden ser consideradas como iguales para todas las aplicaciones ordinarias; pero en otra clase de medidas, como las de líquidos, de la misma denominación difieren notablemente en los dos países. **La medida modelo de longitud** de ambos países es teóricamente la de un péndulo de segundos en el vacío al nivel del mar á la latitud de Londres y á la temperatura de 62° Fahr (16°7 C). La longitud de dicho péndulo se supone dividida en 39.1393 partes iguales, llamadas pulgadas; y 36 de estas pulgadas fueron adoptadas como la yarda modelo de ambos países. Pero habiendo sido destruído por el fuego en 1834 el modelo, se encontró que era imposible reponerlo por medio de la medida de un péndulo. La yarda actual inglesa como está determinada á una temperatura de 62° Fahr (16°7 C) (por el modelo conservado en el Parlamento), es el modelo empleado en el levantamiento geodésico y litoral de los E. U. *(The U. S. Coast and Geodetic Survey)* y está reconocido como modelo en todo el país y departamentos del Gobierno, aun cuando no ha sido declarado así por ningún Acto del Congreso.

**El modelo legal de pesos** de los Estados Unidos es la **libra Troy del cuño de Filadelfia.** Este modelo que contiene 5,760 granos, es una copia exacta de la **libra Troy imperial de la Gran Bretaña.** El *avoirdupois* ó libra comercial de los Estados Unidos que contiene 7000 granos, y se deriva de la libra Troy, modelo del cuño, se ha encontrado de acuerdo, con una aproximación de una milésima de grano, con la libra *avoirdupois* británica. « The U. S. Coast Survey » declara, por tanto, los pesos de los dos países iguales.

**La Tonelada.** En las ordenanzas revisadas de los E. E. W. 2.ª edición, 1878, dice : « Dondequiera que se use la palabra tonelada en este capít, refiriéndose á pesos, se considerará como que significa 20 quintales y cada quintal con un peso de 112 libras *avoirdupois.* » Parece que es ésta la única reglamentación del Gobierno de los E. E. W. sobre la materia.

La ton de 2,240 lbs, con frecuencia llamada tonelada bruta (**gross**), se usa generalmente en el comercio de minerales de hierro, hierro nativo, rieles y otras manufacturas de hierro y acero. El **cok** y otros artículos se comercian por tonelada neta de 2,000 libs. La *(bloom)* tonelada tenía 2.464 lbs=2,240 lbs+2 quintales de 112 lbs; y la de hierro nativo tenía 2,268 lbs=2,240 lbs+un *arenaie (sandage)* de 28 lbs por la arena que quedaba adherida al hierro nativo; pero muchos fundidores sólo concedían 14 lbs. En trabajos de tracción eléctrica la ton representa 2.000 lbs.

**Como volumen** la tonelada se considera conteniendo 252 galones (952.56 litros); para medir maderas en bruto de 40 pies cúb (1,132.60 litros) y para madera labrada, de 50 pies cúb (1,415.77 litros). 252 galones (de los E. E. W.) de agua pesan como 2,100 lbs (952.55 kilogramos); 252 gals Imperiales (ingleses) pesan como 2,500 lbs (1,133.98 kilog). *

**El sistema métrico fué legalizado en los Estados Unidos** en 1866, pero no se ha hecho obligatorio.

El Gobierno ha suministrado luego muy exactos modelos métricos á los diferentes Estados. El uso del sistema métrico se permitió en la Gran Bretaña el 6 de agosto de 1897 y en Rusia en 1900. Su uso es ahora por lo menos permitido en todos los países civilizados. La unidad métrica de longitud es el metro, el cual se supuso ser una diez millonésima $\left(\frac{1}{10,000,000}\right)$ del cuadrante de la tierra, esto es, de la parte de un meridiano, comprendida entre cualquier polo y el ecuador. Esta extensión fué medida y fueron preparados una serie de modelos de pesos

*El sistema métrico comparado con el inglés tiene las mismas ventajas y desventajas que las de nuestro sistema americano decimal de monedas, comparados con el sistema monetario inglés de libras, chelines y peniques. Facilita enormemente todos los cálculos; pero como toda innovación causará necesariamente algunos inconvenientes mientras se efectúa el cambio. El sistema métrico tiene también la lejana y gran ventaja de que tiende á hacerse universal en todas las naciones civilizadas.

y medidas, de acuerdo con el resultado, y depositados en los archivos de Francia, en París (metro de archivos, kilogramos de archivos, etc.). Se ha descubierto desde entonces que ocurrieron errores en los cálculos hechos para determinar la longitud del cuadrante; pero los modelos permanecen sin embargo como se prepararon en su origen.

**Las medidas métricas de superficie y de capacidad** son los cuadrados y cubos del metro y de sus fracciones decimales y múltiples.

**La unidad métrica del peso es el gramo**, que es el peso de un mililitro ó de un centímetro cúbico * de agua pura á la temperatura de su mayor densidad como de 4.5° centígrados ó 40° Fahr.

Por medio de la acción unida de los principales gobiernos del mundo, se ha establecido, con su asiento cerca de París, **una oficina internacional de pesos y medidas**. Se han preparado dos barras puras de platino-iridio y se ha hecho de una de ellas un número de kilogramos (1,000 gramos) modelo y de la otra un número de metros modelo, derivados ambos de los modelos de los Archivos de Francia. De estos algunos fueron seleccionadas como modelos internacionales y los otros distribuídos entre los diferentes gobiernos. Los enviados á los Estados Unidos están en poder de la *U. S. Coast Survey*.

La determinación del equivalente del metro en medida inglesa es asunto muy difícil. El *metro* modelo es medido de extremo á extremo de una barra de platino ó 0° C, mientras que la *yarda* modelo se mide *entre dos líneas* trazadas en una escala de *plata* incrustada en una barra de bronce y á 62° F (16°7 C) *The Unities States Coast Survey*† adopta por longitud del metro á 62° Fahr (16°7 C) el valor determinado por el capitán *A. R. Clarke* y el coronel *Sir Henry James*, en 1866. á saber: 39.370432 pulgadas (=3.2808666 pies=1.0936222 yarda); pero el equivalente legal establecido por el Congreso es 39.37 pulgadas (=3.28083 pies = 1.093611 yardas). Este valor es tan exacto como puede deducirse con los datos de que se dispone.

**El gramo pesa** según la determinación del profesor *W. H. Miller* ‡ 15.43234874 granos. Un examen hecho en la oficina internacional de pesos y medidas en 1884 lo hace igual á 15.43235639 granos. El **valor legal** en los Estados Unidos es 15.432 granos.

---

* Un centímetro = $\frac{1}{100}$ metro = .3937 pulgadas. Un mililitro ($\frac{1}{1000}$ litro) ó centímetro cúbico = .061 pulgadas cúbicas.

† Apéndice número 22 al informe de 1876, pág. 6.

‡ Transacciones filosóficas, 1856, págs. 893, etc.

## Valores aproximados de las monedas extranjeras en dinero de los Estados Unidos.

**Las referencias** (1, 2, 3 y 4) están en las notas al pie.

De la circular del Departamento del Tesoro, oficina del cuño de los Estados Unidos, enero 1.º de 1887, de la « Cuestión monetaria », por H. Costes, París, 1884, y de nuestra décima edición.

República Argentina. Peso=100 centavos, 96.5 cts[2-3]. Argentino=5 pesos, $4.82.

Austria. Florín=100 kreutzer, 47.7 cts[2], 35.9 cts[3]. Ducado, $2.29. María Teresa *Thaler* ó *Levantín*, 1780, $1.00[3]. *Rix Thaler* 97 cts[4]. Soberano, $3.57[4].

Bélgica. Franco=100 céntimos, 17.9 cts[2], 19.3 cts[3].

Bolivia. Boliviano=100 céntimos, 96.5 cts[2], 72.7 cts[3]. Onza, $14.95. Dólar 96 cts[4].

Brasil. Milreis=1,000 reis, 50.2 cts[2] 54.6 cts[3].

Canadá. Moneda de los Estados Unidos é inglesa. También la libra, $4[4].

Centro América[4]. Doblón $14.50 á 15.65. Real, término medio, 5 3/4 cts. (Véase Honduras.)

Ceylán. *Rupee*, lo mismo que en la India.

Chile. Peso=10 dineros ó décimos=100 cts, 96.5 cts[2], 91.2 cts[3]. Condor=dos doblones=5 escudos=10 pesos. Dólar, 93 cts[4].

Cuba. Peso 93.2 cts[3]. Doblón, $5.02.

Dinamarca. Corona=100 oro, 25.7 cts[2], 26.8 cts[3]. Ducado, $1.81[4]. *Skilling* 3/4 cts[4].

Ecuador. Sucre, 72.7 cts[3]. Doblón, $3.86. Condor, $9.65. Dólar, 93 cts[4]. Real 9 cts[4].

Egipto. Libra=100 *piastres*=4,000 *paras*, $4.94,33[3].

Finlandia. *Markka*=100 *penni* 19.1 cts[3] 10 *markkaa*, $1.93.

Bulgaria (Principado de). 5 *leva*=96.5 cts[3]. 1 *lew*=17.95 cts[3]. 50 stotinkis=8.88 cts[3].

Francia. Franco=100 céntimos, 17.9 cts[2], 19.3 cts[3]. Napoleón $3.84[4]. Libra 18.5 cts[4]. Centavo 1 cts[4].

Alemania. Marco=100 pfennigs, 21.4 cts[2], 23.8 cts[3]. Augusto (Sajonia) $3.98[4]. Carolina (Baviera), $4.93[4]. Corona (Baden, Baviera, N. Germania), $1.06[4]. Ducado (*Hamburg Hanover*), $2.28[4]. Florín (Prusia, Hanover), 55 cts[4]. *Groschen*, 2.4 cts[4]. *Kreutzer* (Prusia), 0.7 cts. Maximiliano (Baviera), $3.30[4]. *Rix Thaler*, (Hamburg Hanover), $1.10[4] (Baden Brunswick), $1.00[4] (Prusia *N. Germany*, Bremen, Sajonia, Hanover), 69 cts[4].

Gran Bretaña. Libra esterlina ó Soberano (£)=20 chelines=240 peniques, $4.86.65[3]. Guinea=21 chelines. Corona=5 chelines. Chelin(s) 22.4 cts[2], 24.3 cts (1/20 de libra esterlina). Penique (d), 2 cts.

Grecia. *Drachma*=100 *lepta*, 17 cts[2], 19.3 cts[3].

Haití. Gourde de 100 cts 96.5 cts[2,3].

Honduras. Fuerte ó Peso de 100 centavos $1.01. (Véase Centro América.)

India. *Rupee*=16 *annas*, 45.9 cts[2], 34.6 cts[3]. *Mohur*=15 *rupees*, $7.10. *Star pagoda* (Madras), $1.81[4].

Italia, etc.[4] Lira=100 *centésimos*, 17.9 cts[2], 19.3 cts[3]. *Carlin* (Cerdeña), $8.21[4]. Corona (Sicilia), 96 cts[4]. Libra (Cerdeña), 18.5 cts[4].(Toscana, Venecia), 16 cts[4]. Onza (Sicilia), $2.50[4]. Paolo (Roma), 10 cts[4]. Pistola (Roma), $3.37[4]. Escudo[4] (Piamonte), $1.36. (Génova) 1.28, (Roma) $1.00 (Nápoles, Sicilia) 95 cts. (Cerdeña), 92 cts. Teston (Roma), 30 cts[4]. *Zecchino* (Roma), $2.27[4].

Japón. *Yen*=100 *sen* (oro) 99.7 cts[1] (plata) $1.04[2], 78.4 cts[3].

Liberia. Dólar $1.0034.

México. Dólar ó peso=100 centavos (oro) 98.3 cts, (plata), $1.05[3], 79 cts[3]. Onza ó doblón=16 pesos $15.74.

Países Bajos. Florín de 100 cts, 40.5 cts[2], 40.2 cts[3]. *Ducatoon*, $1.32[4]. *Guilder*, 40 cts[4]. *Rix dólar*, $1.05[4]. *Stiver*, 2 cts[4].

Nueva Granada. Doblón $15.34[4].

Noruega. Corona=100 *(ore)*=30 *skillings*, 25.7 cts[2], 26.8 cts[3].

Paraguay. Peso=8 reales, 90 cts.

Persia. *Thoman*=5 *sachib* — *kerans*=10 *banabats*=25 *abassis*=100 *scahis*, $2.29.

Perú. Sol=10 *dineros*=100 cts 96.5 cts[2]. 72.7 cts[3]. Dólars, 93 cts[4].

Portugal. *Milreis*=10 *tostones*=1,000 *reis*, $1.08[3]. Corona=10 *milreis*. *Moidore* $6.50[4].

Rusia. Rublo=2 poltinniks=4 tchetvertaks=5 abassis=10 griviniks=20 pie.

taks=100 kopecks, 77 cts[2], 58.2 cts[3]. Imperial=10 rublos, $7.72. Ducado=3 rublos, $2.39.

Islas de Sandwich. Dólar, $1.00[2].

Sicilia. (Véase Italia.)

España. Peseta=100 céntimos, 17.9 cts[2], 19.3 cts[3]. Doblón (nuevo)=10 escudos=100 reales, $5.02. Duro=2 escudos[2], $1.00[2]. Doblón (viejo), $15.65[4]. (Casi todo este sistema ha desaparecido.) Pistola=2 coronas, $3.90[4]. Peso, $1.04[4]. Real de plata 10 centavos[4]. Real de vellón 5 cts[4].

Suecia. Corona=100 ore, 25.7 cts[2], 26.8 cts[3]. Ducado, $2.20[4]. *Rix Dólars*, $1.05[4].

Suiza. [1] Franco=100 céntimos, 17.9 cts[2], 19.3 cts[3].

Trípoli. Mahbub=20 pesos, 65.6 cts[3].

Túnez. Peso=16 *karobos*, 12 cts[3]. 10 pesos, $1.16.6.

Turquía. Peso, 40 *paras*, 4.4 cts[3]. *Zecchin*, 1.40[1].

Colombia. Peso=10 décimos=100 centavos, 96.5 cts[2], 72.7 cts[3]. Condor=10 pesos, $9.65. Dólar, 93.5[4] cts.

Uruguay. Peso=100 centavos ó centésimos (oro), $1.03 (plata), 96.5 cts[2].]

Venezuela. Bolívar=2 reales, 17.9 cts[2], 19.3 cts[3].

1. Francia, Bélgica, Italia, Suiza y Grecia forman la unión latina. Sus monedas son parecidas en diámetro, peso y finura.

2. 19.3 veces el valor de una moneda sencilla en francos, según la de Costes.

3. Cambio á la par ó valor equivalente en términos de dólars de oro de los Estados Unidos (Circular del Tesoro).

4. De nuestra décima edición.

**El oro perfectamente** puro vale $1, los 23.22 grs=$20.67183 la onza troy=$18.84151 la onza *avoir*. El **Standard** (moneda de los E. U.) vale $18.60465 por onza troy=$16.95736 por onza *avoir*. Consta de 9 partes de peso de oro puro y 1 parte de aleación. Su valor es el del oro puro solamente; porque han sido pagados por el gobierno los gastos de la liga y de la acuñación.

El oro puro se llama fino ú oro de 24 *quilates;* y cuando se liga; la liga se supone dividida en 24 partes en peso, y según sean 10, 15 ó 20, etc., de estas partes de oro puro, se dice que la liga es de 10, 15 ó 20, etc., *quilates*.

**El término medio de la pureza del oro nativo de California**, por algunos millares de ensayos hechos en el cuño de los Estados Unidos en Filadelfia, es 88.5 partes de oro 11.5 de plata. Para algunos de Georgia, 99 % oro.

**La plata pura** fluctúa en valor; así, durante 1878, 1879 fluctuó entre $1.5 y $1.18 la onza *troy* ó $.957 y $1,076 por onza *avoir*.

---

*N. del T.* — Aunque muchas de las medidas que van á continuación son exclusivamente inglesas, como las relaciones entre los países que usan este sistema con los que usan el métrico, aumentan día por día, hemos querido dejarlas tal como están en el texto.

### Peso troy de los E. U. y de la Gran Bretaña.

| | |
|---|---|
| 24 granos..... | 1 *pennyweight*, dwt. |
| 20 pennyweights..... | 1 onza=480 granos. |
| 12 onzas..... | 1 libra=240 *pennyweights*=5,760 granos. |

**El peso troy se usa para oro y plata. Un quilate** de los joyeros, para piedras preciosas es, en los Estados Unidos=3.2 granos; en Londres 3.17 grns; en París 3.18 grns, dividido entre 4 granos de joyeros. En los pesos **troy**, los de boticarios y en el **avoirdupois, el grano es el mismo.**

### Peso americano y británico de los boticarios.

| | |
|---|---|
| 20 granos..... | 1 escrúpulo. |
| 3 escrúpulos.... | 1 dracma=60 granos. |
| 8 dracmas..... | 1 onza=24 escrúpulos=480 granos. |
| 12 onzas..... | 1 libra=96 dracmas=288 escrúpulos=5,760 granos. |

En peso troy y de boticario, el grano, onza y libra son los mismos.

## Peso avoirdupois ó comercial de los Estados Unidos y de la Gran Bretaña.

| | |
|---|---|
| 27.34375 granos..... | 1 dracma. |
| 16 dracmas..... | 1 onza=437½ granos. |
| 16 onzas..... | 1 lib=256 dracmas=7,000 granos. |
| 28 libras..... | 1 cuarto=448 onzas. |
| 4 cuartos..... | 1 quintal=112 lib. |
| 20 quintales.... | 1 tonelada=80 cuartos=2,240 lib. |

**1 stone**=14 libras; **1 quintal**=100 libras **avoir.**

**El modelo de la libra avoirdupois**, que es la que está en uso comercial común, es el peso de 27.7015 pulgadas cúbicas de agua destilada pura á su mayor densidad á 39º2 Fahr (4º C) en la latitud de Londres, al nivel del mar y á la presión de 760 mm (ó sean=.453593 kilogramos). Pero esto adolece de error como de 1 en 1,362.

**Una libra troy**=.82286 de lib **avoir**; 1 libra avoir=1.21528 libra troy ó de boticario.

**Una onza troy**=1.09714 onza avoir; 1 onza avoir=.911458 onza troy ó de boticario.

## Medida de longitud de los Estados Unidos y Gran Bretaña*.

| | |
|---|---|
| 12 pulgadas. | 1 pie=.3047973 de metro. |
| 3 pies..... | 1 yarda=36 pulg=.9143919 de metro. |
| 5½ yardas. | 1 pértica ó percha=16½ pies=198 pulg=5.02 mets. |
| 40 pértica.. | 1 estadio=220 yardas=660 pies=201.17 mets. |
| 8 estadios.. | 1 milla leg ingl=320 pértic=1,760 yard =5,280 pies = 63,360 pulg. |
| 3 millas.... | 1 legua=24 estadios=960 pértica=5,280 yards =15,840 pies = 4828.03 metros. |

**1 punto**=$^1/_{72}$ de pulg; **1 línea**=6 puntos= $^1/_{12}$ de pulg; **1 mano**=4 pulg; **1 palmo**=9 pulgadas.

**1 brazada**=6 pies. **1 cable**=120 brazadas=720 pies; **1 cadena** de agrimensor de **Gunter** tiene de largo 66 pies ó 4 pértica. Tiene 100 eslabones de 7.92 pulgadas de largo. Ochenta cadenas de **Gunter**=1 milla. (*N. del T.* — La pulgada tiene .0253954 metros.)

**1 milla marina geográlica ó nudo** se define diversamente como = á la longitud de

| | metros. | pies. | milla legal. |
|---|---|---|---|
| 1 minuto de *longitud* en el Ecuador = | 1,855.345 | 6,087.15 | 1.15287 |
| 1 — de *latitud* en el Ecuador = | 1,842.787 | 6,045.95 | 1.14507 |
| 1 — — en el polo = | 1,861.655 | 6,107.85 | 1.15679 |
| 1 — — á la latitud 45º = | 1,852.181 | 6,076.76 | 1.15090 |
| 1 — de un círculo máximo de una verdadera esfera cuya área sea igual á la de la tierra. = | Valor adoptado por **U. S. Coast and Geodetic Survey** 1,853.248 | 6,080.27 | 1.15157 |
| Milla ó nudo del **Almirantazgo británico.** = | 1,853.169 | 6,080.00 | 1.15152 |

Las anteriores longitudes de minutos, en metros y pies, son las publicadas por The U. S. Coast and Geodetic Survey en el apéndice n.º 12 del informe de 1881 y están calculados del esferoide de Clarke que es ahora el modelo en aquel cuerpo.

En el ecuador, **1º de latitud es**=68.70 millas terrestres á la latitud de 20º=68.78; á 40º=69.00; á 60º=69.23; á 80º=69.39; á 90º=69.41.

---

* *N. del T.* — Hemos agregado las equivalencias métricas.

**Largo de 1. grado de longitud en diferentes latitudes y al nivel del mar.** Estos largos son en millas terrestres comunes de 5,280 pies (=1,609.35 metros). Como la figura de la tierra no se ha determinado nunca exactamente, no son sino aproximaciones. Las intermedias pueden encontrarse correctamente por una simple proporción; 1º de longitud corresponde á 4 minutos de tiempo y 1 minuto de longitud á 4 segundos.

| Gr. de lat. | Millas. | Gr. de lat. | Millas. | Gr. de lat. | Millas. | Gr. de lat. | Millas. | Gr. de lat. | Millas. | Gr. de lat. | Millas |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 0 | 69.16 | 14 | 67.12 | 28 | 61.11 | 42 | 51.47 | 56 | 38.76 | 70 | 23.72 |
| 2 | 69.12 | 16 | 66.50 | 30 | 59.94 | 44 | 49.83 | 58 | 36.74 | 72 | 21.43 |
| 4 | 68.99 | 18 | 65.80 | 32 | 58.70 | 46 | 48.12 | 60 | 34.67 | 74 | 19.12 |
| 6 | 68.78 | 20 | 65.02 | 34 | 57.39 | 48 | 46.36 | 62 | 32.55 | 76 | 16.78 |

### Medidas de superficie ó medidas agrarias británicas y de los Estados Unidos.

144 pulgadas cuadradas=1 pie cuadrado (=.0929 mets. cuad.), (cien (100) pies cuadrados=**1 Square**) (=9.289968 met. cuad.). (*Obs. del T.* — No hay en español medida usada que equivalga al **Square**.)

9 pies cuadrados=1 yarda cuadrada=1,296 pulg cuad. (=.836.126 m cuad).

30 $^{1}/_{4}$ yardas cuadradas=1 pértica cuadrada=272 $^{1}/_{4}$ pies cuad. (=25.29 met. cuad.).

40 pérticas cuadradas=1 *rood* ($^{1}/_{4}$ de acre cuadrada)=1,210 yards cuad.

4 rood=1 acre =160 pérticas=4,840 yards cuad.=43,560 pies cuadrados.

640 acres=1 milla cuadrada.

**Los terrenos** públicos de los E. E. W. están divididos en **townships** (*N. del T.* — No tiene equivalente en español. Son cuadrados de 6 millas (9,656 mts) por lado, limitados por paralelos y meridianos.) Nominalmente cada **township** contiene 36 **secciones** de una milla cuadrada cada una y éstas á su vez cuatro **cuartos de sección** de .5 milla en cuadro cada una. Por **la ley**, los errores, incluyendo los de la convergencia de los meridianos, deben cargarse á los cuartos de sección al norte y al oeste del **township**.

### Medidas imperiales británicas para líquidos y para áridos.

Este sistema está establecido en toda la Gran Bretaña con exclusión de las antiguas. Su base es el galón imperial de 277.274 pulgs cúbs (4.543 lit) ó sean 10 lbs avoir (4.535927 kilog) de agua pura á la temperatura de 62º F (16º6 C) cuando el barómetro está á 30 pulgs (762 mm). **Esta base tiene un error** como de 1 en 1836, porque 10 lbs (4.535927 kilog) de agua equivalen solamente á 277.123 pulgs cúbs.

(*N. del T.* — En esta tabla hemos agregado las equivalencias en sistema métrico.)

| | | Libras avoir de agua. | Peso en kil. á 62 ° F. ó sean 16 66 C y barómetro á 30 pulg. | Pulg. cúb. | Litros. | Pies cúb. | Lado del cubo de igual capacidad. — Pulgs. | Lado del cubo de igual capacidad. — Centím. |
|---|---|---|---|---|---|---|---|---|
| 4 *gills* | 1 pinta... | 1.25 | .567 | 34.6592 | .568 | ..... | 3.2605 | 8.2816 |
| 2 pintas | 1 *quart*... | 2.50 | 1.134 | 69.3185 | 1.136 | ..... | 4.1079 | 10.4338 |

Medidas de áridos

*N. del T.* — El peso del agua á la temperatura de 62º F (16º6 centg) con el barómetro á 30 pulgs (762 mm) es = 62.355 lbs el pie cúb = .99889 kilgms el litro; á la temperatura de 4º centg, sobre cero, con barómetro á 76 cent, es = 1 kilogramo el lit.
El galón imperial = .16046 pies cúb.

n. significa característica negativa.

(*N. del T.* — Hemos agregado las equivalencias métricas que siguen.)

| | Litros. |
|---|---|
| *Gill* | .14206 |
| Pinta | .56824 |
| *Quart* | 1.13649 |
| Galón | 4.54596 |
| *Peck* | 9.09192 |
| *Bushel* | 36.3677 |
| Quarter | 290.9416 |

| | Gramos. |
|---|---|
| Dragma *avoir dupois* | 1.771836 |
| Onza | 28.349375 |
| Libra | 453.59265 |
| *Hundred weight* | 50,802.35 |
| Tonelada | 1,016,047.0 |
| Grano Troy | .06479 |
| *Penny weight* | 1.5552 |
| Onza | 31.10346 |
| Libra | 373.2419 |

El peso del agua nos ofrece un medio sencillo de encontrar el volumen de un envase. Pésese primero el envase solo y después lleno de agua. La diferencia será el peso del agua, y éste dividido por el número de kilogramos por metro cúbico correspondiente á la temperatura del agua que indicamos en la tabla siguiente, será la capacidad en metros cúbs de dicho envase (estando a nivel del mar).

| Temp. Fahr. | Temp. Centíg. | Kilog por $m^3$ |
|---|---|---|
| 32° | 0° | 999.879 |
| 40° | 4°4 | 999.975 |
| 50° | 10° | 999.751 |
| 60° | 15°6 | 999.078 |
| 70° | 21°1 | 998.037 |
| 80° | 26°7 | 996.691 |
| 90° | 32°2 | 995.106 |
| 212° | 100° | 956.355 |

Cuando no se requiera tan extremada precisión puede calcularse el peso de metro cúbico de agua en 1,000 kilogs que es el que corresponde á la temperatura de 4° C.

## Medidas métricas de longitud según modelos de los Estados Unidos é ingleses.

**Pesos métricos reducidos á peso comercial ordinario ó Avoir de 1 libra=16 onzas ó 7,000 granos.**

| | Granos. |
|---|---|
| Miligramos | .015432 |
| Centigramos | .15432 |
| Decigramos | 1.5432 |
| Gramo | 15.432 |
| | Libras avoir. |
| Decagramo | .022046 |
| Hectogramo | .22046 |
| Kilogramo | 2.2046 |
| Miriagramo | 22.046 |
| Quintal * | 220.46 |
| Tonelada | 2,204.6 |

El gramo es la base de los pesos franceses; y es el peso de un centímetro cúbico de agua destilada á su mayor densidad, al nivel del mar, á la latitud de París, barómetro 29.922 pulgadas ($^{m}0.76$).

## Rusas.

(*N. del T.* — Siempre introducimos el sistema métrico.)

**El pie**, lo mismo que el pie de los E. U. ó pie británico. **Sachine**=7 pies=$=2^{m}.13356$. **Verst**=500 sachine=3,500 pies=1,166 $^{2}/_{3}$ yardas=.6629 de milla=1,066.78 metros. **Pood**=36,114 libras *avoirdupois*=(16,381 kilogramos)

## Españolas.

**El castellano** de España y Nueva Granada, para pesar oro es diversamente estimado entre 71.07 á 71.04 granos (4.605 á 4.603 gramos). A 71.055 granos (4.604 gramos) (término medio entre los dos) 1 *avoirdupois* ú onza comercial ordinaria contiene 6.1572 castellanos; y 1 libra *avoirdupois* contiene 98.515. También una onza troy es=6.7553 castellanos y 1 libra troy es=81.064 castellanos. Tres dólares de oro de los E. U. pesan como 1.1 castellanos.

**El marco español** para metales preciosos, debe tomarse en la práctica, en Sud América, por .5065 de 1 libra *avoirdupois* (.2297 kilog). En España, 0.5076 de la mayor parte de ellos están sin embargo entre .5 y .54 de 1 libra *avoirdupois* (.227 y .243 kilog). El .5065 de 1 libra (.2297 kilog) es=3545½ granos; y .5076 de libra (.230 kilog) es=3553.2 granos. Un marco=50 castellanos=400 *tomines*=4800 granos de oro español.

**La arroba** tiene varios valores en diferentes partes de España. La de Castilla ó Madrid es 25.4025 *libras avoirdupois* (11.522 kilog); **la tonelada** de Castilla es=2032.2 libras *avoirdupois* (921.79 kilog); **el quintal** es=101.61 libras *avoirdupois* (46.089 kilog); **la libra** es=1.0161 libras *avoirdupois* (0.4608 kilog); **la cántara** de vino etc., de Castilla es=4.263 galones de los E. U. (16.11 litros) la de la Habana es=4.1 galones (15.50 litros).

**La vara** de Castilla ($^{m}$83591) es=3.8748 pulgs ó casi 32 $^{7}/_{8}$ pulgs justas; ó 2 pies 8 $^{7}/_{8}$ pulgs. **La fanegada** de terreno desde el año de 1801 es=1.5871 acres=69134.08 pies cuad (.64225 hectáreas). **La fanega** de granos, etc., es=1.59914 *bushel* raso de los E. U. En California **la vara legal** es=33.372 pulgs de los E. U. ($0^{m}847633$); y **la legua** es=5,000 varas, ó 2.6335 millas de los E. U.

# TABLAS DE CONVERSIÓN PARA UNIDADES DE MEDIDAS, PESOS, etc. (Introducción).

En las tablas que siguen las cifras decimales que se repiten están indicadas por un *. Así : 1.2*01=1.201010101...

**Los valores exactos** están indicados por un †. Así : 12† pulg=1 pie; 1 metro=.001† kilómetro.

**Las características negativas** se indican por la letra n. Así: n 1.2855573=$\overline{1}$.2855573=.2855573 — 1=9.2855573 — 10. Véase pág. 74 para el uso de los logaritmos.

La cadena y eslabones de Gunter y de Ingenieros, se distinguen por una G, y una I. Así : una cadena G=66† pies; 1 eslabón I=1† pie.

La tabla A contiene ecuaciones que tienen por base las equivalencias de las tablas de 1 á 36.

En la tabla C se dan números y equivalentes de uso común para transformar las ecuaciones como se explica abajo.

Cada tabla ha sido calculada independientemente por dos personas, á lo menos, y sus resultados comparados. Uno de estos trabajos se dió como copia al compositor y las pruebas fueron corregidas por el otro.

Los cálculos comprenden muchas veces el número de las ecuaciones que aquí se dan, y de haber publicado una considerable proporción de estos cálculos, se habría hecho una tabla demasiado voluminosa para un formulario de bolsillo.

Con poca práctica, el lector puede, no obstante, encontrar muchas otras equivalencias por medio de estas que se dan. Al hacer esto, los logaritmos dados en la tabla C serán muy útiles.

Supongamos que se desee la longitud del metro en *rods*. En la tabla 1 (longitud) ó en la C (equivalentes de uso común) se encuentra.

1 met=3.28083 pies, Log .515 9842

y en la tabla 1 se encuentra :

1 pie=.*0606 *rod*, Log n 2.782 5161

Sumando los logaritmos se encuentra :

1 metro=.19884 *rod*, Log n 1.298 5003

Otros ejemplos : 1 met por seg=? millas por día.

Tabla 18 (longitud por tiempo ó velocidad) da :

1 metro por seg=2.23693 millas por hora. Log .349 6528

y la tabla 5 (tiempo) ó la C dan :

1 día 24 horas Log 1.380 2112

Sumando logs se tiene :

1 met por seg=53.686 millas por día. 1.729 8640

En algunos casos de uso frecuente damos dos tablas, conteniendo cada una el *inverso* de los valores de la otra; así damos « Pesos de los volúmenes » (como 1 pie cúb=? lbs) y « Volúmenes de los Pesos » (como 1 lb=? pies cúbs) de agua. Cuando sólo uno de los dos inversos está dado, el otro se deduce muy fácilmente del conocido. (Véase la primera *Advertencia.*)

Log 1 .000 0000

1 pie por seg=720 pulgs por min Log 2.857 3325

1 seg por pie=.0013*888 min por pulg. Log n 3.142 6675

**Advertencia**. Debe observarse que aunque un cuerpo moviéndose 1 pie por seg (=720 pulgs por minuto) necesita 1 seg para recorrer un pie (.0013*888 min para 1 pulg) y aunque 1 pie por seg y 1 seg por pie son numéricamente iguales, no son en realidad idénticos sino inversos. Así, también,

1 real por dólar=1 : 10

pero, 1 dólar por real=10 : 1

Seleccionando las equivalencias para publicarlas, hemos preferido, en general, aquellas que no pueden fácilmente encontrarse por otras de la misma tabla ó con tablas muy simples. Así al dar en la tabla 12 (Peso por superficie) el equivalente de kilogramo por centím cuad, en lbs por pulgs cuad, se omitió el equivalente en lbs por pie cuad que se encuentra usando la tabla 2 (Superficies) del equivalente dado en libras por pulgs cuad.

Lo mismo el equivalente de una presión de 1 lb por pulg cuad en onzas por pulg cuad ó en lbs por pie cuad, no se dió en la tabla 12 (Pesos por superficie); porque se deducen de 1 lb por pulg cuad por

* Decimales que se repiten. † Valores exactos. n, Característica negativa. I, Ingenieros. G, Gunter.

medio de la tabla 4 (Pesos) y de la tabla 2 (Superficies) respectivamente.

Como las relaciones entre los valores de las monedas de distintas naciones cambian con frecuencia, los equivalentes de las tablas 25 á 30 inclusive, (Valores) pueden ser algunas veces simplemente aproximadas.

Sus logs se dan solamente hasta la tercera decimal, no obstante habérselos calculado hasta la 7.ª Cuando se quiera más aproximación úsense los logs de 4 decimales, págs 80 y 81.

### Lista de las tablas (índice).

| | | Págs. |

| $g$=aceleración debida á la grav= | 9.81 | metros por segundo por segundo (e) | .991 6690 |
| 1 £= | $4.86 | (f) | .686 6363 |
| 1 franco= | $ .193 | (f) | n 1.285 5573 |
| 1 marco= | $ .238 | (f) | n 1.376 5770 |

(a) Véase pág. 229.

(b) Véase Densidad del aire, pág. 335.

★ Decimales que se repiten. ‡ Valores exactos. n, Característica negativa. I, Ingenieros. G, Gunter.

(c) 1 pulgada de mercurio=13.5956 de agua. Valor adoptado por la « Oficina internacional de pesos y medidas ». Lat 45°. A nivel del mar. El mercurio á 0° C=32° Fahr.

(d) 1 lb Fahr=778 pies-lbs. De acuerdo con la determinación muy cuidadosa hecha por el profesor Henry A. Rowland, aceptada generalmente como tipo.

(e) $g$=9 m. 81 por seg por seg; generalmente aceptada como término medio. A la lat de 45° y á nivel del mar, $g$=9.806056 m.

Para otras latitudes L y alturas $h$, en centímetros;

$g$ en cent por seg por seg=aproximadamente 980.6056 — 2.5028 cos 2 L — .000003 h.

(f) De acuerdo con la circular del Departamento de la Tesorería de los E. U., enero 1 de 1887, £ 1=$4.8665 oro; 1 franco=.193; 1 marco=$.238.

## Pendientes.

**Véanse las tablas y figs.** de las páginas que siguen.

**Altura** del plano=$v$; **longitud** del plano=$s$; **distancia horizontal** ó base del plano=$h$; ángulo del plano con la horizontal=A (que lo seguiremos llamando *ángulo del plano*), sen A=$v/s$; cos A=$h/s$; tang A=$v/h$; cot A=$h/v$; sec A = $s/h$; cosec A=$s/v$.

Para ángulos pequeños.

$v = s$ . sen A = $h$ . tang A = $h \div$ cotang A = $s \div$ cosec A | $v =$ .01745 $s$ A°
$s = v \div$ sen A = $h \div$ cos A = $h$ . sec A = $v$ . cosec A | $s =$ 57.30 $v \div$ A°
$h = s$ . cos A = $v \div$ tang A = $v$ . cot A = $s \div$ sec A | $h =$ 57.29 $v \div$ A°

**La relación entre los 3 lados del plano inclinado para un ángulo de 1°**, están indicadas en las 3 figs. después de la tabla que sigue en que el ángulo de 1° está necesariamente muy exagerado. **Para ángulos pequeños**, puede suponerse que la altura del plano varía en proporción con el ángulo; y la longitud y distancia horizontal para una altura dada, en razón inversa del ángulo.

### Tabla de alturas del plano en metros para 100 metros, horiz correspondientes á diferentes ángulos de inclinación.

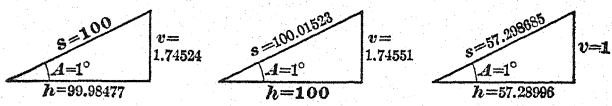
**Hasta en pendientes** de 1°38′=1 en 35=2.85% (véase tabla) pueden bajar los caballos trotando rápidamente con seguridad. En caminos de montaña se llega hasta 3° (=5.24 por ciento) y 5° (=8.75 por ciento). No se debe pasar de 2½° (=4.36 por ciento), á menos que sea absolutamente necesario.

**Cualquier dist horizontal** =longitud del plano × cos A
— **longitud del plano**=distancia horizontal ÷ cos A
— **altura del plano** =distancia horizontal × tang A
ó bien=longitud del plano × sen A.

A una pediente de *n* pies ó metros de altura para 100 pies ó metros, respectivamente, de dist horizontal, se la llama **pendiente de *n* por ciento.**



## Dimensiones relativas de los lados del plano inclinado para una pendiente de 1°.

## PENDIENTES EN METROS PARA 100 METROS HORIZONTALES

Las fracciones de minutos se dan solamente hasta 34 mets para 100.

Un **eclímetro** graduado por la 3.ª columna y numerado por la primera, dará á la vista las pendientes en mets para 100 mets. No hay errores. Original del autor.

Tratándose de las **pendientes en los ferrocarriles** se acostumbra, como en nuestra tabla, determinarla por la relación entre la altura A y la distancia

horizontal B. Así se tiene $\frac{A}{B}$ = tang $a$ (ángulo que forma el plano con la horizontal). Cuando se establece la relación entre la altura A y la longitud del plano C se tiene $\frac{A}{C}$ = sen $a$; y esta fracción es proporcional á la componente S del peso W en la dirección de la pendiente. Así en una pendiente en que la altura A = .1 × longitud C, se tendrá que sen $a = \frac{A}{C} = .1$; y S = .1 W. La tang $a$ es sólo aproximadamente proporcional á S; pero las pendientes recorridas con tracción sola-

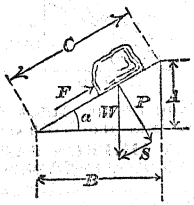

Fig. 78.

mente, aun en los tranvías eléctricos, rara vez exceden á 13 ó 15 por ciento, y en estos casos el error debido á usar tang $a$ en lugar de sen $a$, es menor que una diferencia de .2 por ciento en la pendiente y como de 1 por ciento en el verdadero valor de S. Para pendientes muy fuertes como las de los ferrocarriles de cremallera, debe especificarse siempre si se trata del seno ó de la tang del ángulo $a$.

Las **pendientes transversales**, como las de los movimientos de tierra, se dan, á veces, como en los ferrocarriles; así : $\frac{\text{altura vert}}{\text{dist horizontal}}$ $\frac{A}{B}$, pero usualmente se da invertida $\frac{\text{dist horizontal}}{\text{altura vert}}$, $\frac{B}{A}$. En este caso $\frac{B}{A}$ = cotang del ang $a$ con la horizontal ó tang del ángulo con la vertical que es = (90°-$a$).

## Tabla de cargas ó alturas de agua correspondientes á presiones dadas.

El agua en su mayor densidad, 62.425 libras por pie cúbico = 1 gramo por centímetro cúbico; corresponde á una temperatura de 4° centígs = 39°.2 Fahr.

Carga en pies = 2.306768 × presión en libs por pulg cuadrada.
— — = .0160192 × presión en libs por pie cuadrado.

*Obs. del T.* — N.° 1. En sistema métrico tenemos : Presión en kilogramos por metro cuadrado = carga en metros × 1,000, de donde se deduce que la **carga en mets es** = .001 × *presión en kilgms por met cuad*, con cuya fórmula se hace innecesaria la construcción de una tabla, por la sencillez del cálculo. Ej. : ¿A qué carga corresponde una presión de 105,464.96 kilogms por met cuad. Tendremos que la carga en met es la milésima parte de esta presión ó sea 105.465 mets.

N.° 2. Para algún caso en que se quiera relacionar *algunos de estos datos en el sistema métrico con los de* medidas inglesas ó *viceversa*, recuérdese que para convertir *libras por pulgadas cuadradas en kilogramos por centímetro cuad*, se multiplican aquéllas por .07039. Para convertir *pies en metros* se multiplican aquéllos por .30479.

Para las conversiones contrarias : *kilogramos por centímetro cuad* en *libras por pulg cuad*, se multiplican aquéllos por 14.2228; y para convertir *metros en pies*, se multiplican aquéllos por 3.2809.

## TABLA DE PRESIONES CORRESPONDIENTES Á CARGAS DE AGUA DADAS

El agua en su mayor densidad pesa á razón de 62.425 lbs por pie cúb = 1 gramo por cent cúb = 1 kilogramo el litro; á la temperatura de 4° centígrados = 39°2 Fahrenheit.

Presión en lbs por pulg cuad = .433507 × carga en pies.
Presión en lbs por pie cuad = 62.425 × carga en pies.

*N. del T.* Presión en kilgms por met cuad = 1,000 × carga en mets.
Presión en kilgms por cent cuad = .1 × carga en mets.

Las presiones correspondientes á cargas no dadas en la tabla pueden encontrarse por medio de estas fórmulas, ó deducirse de dicha tabla por una simple proporción.

| Carga. | Presión. | | Carga. | Presión. | |

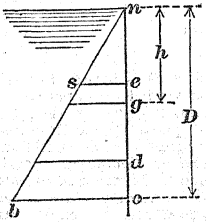
*N. del T.* — Véanse « Obs. del T. » pag 266.

*Obs. del T.* — De igual modo que para hallar la carga en unidades métricas, tampoco es necesario una tabla para encontrar la presión, pues basta para hallar la presión en kilogramos por metro cuadrado multiplicar por 1,000 la carga en metros, ó mutiplicándola por .1 la obtenemos en kilogramos por centímetro cuadrado. Ej. : ¿Qué presión por metro cuadrado produce una carga de 11.2774 met? Según lo dicho, tendremos : 11.4774 × 1,000 = 11277.4 kilogms por met cuad.

Otro ej. : ¿Qué presión por centím cuad nos dará una carga de .304794 met (12 pulgs)? Conforme á la fórmula, tendremos :

.304794 × .1 = .0304794 kilogms por cm cuad.

**Presión total P** contra un plano vertical, *no*, de un ancho igual á la unidad, *y*, perpendicular al papel y de profundidad D = *no*, á contar del nivel del agua *n*.



Area de la superficie plana = *a* = D = 2 *h*; *h* = distancia de la superficie *n* al centro de gravedad, *g*, del plano *no*. El agua en su máximum de densidad, ó peso *w* = 1 gramo por cm cúb = 62.425 lbs por pie cúb á la temperatura de 4° C = 39°2 F.

Sea *bo* = *w*D = á la unidad de presión á la profundidad D. Entonces $P = \frac{wD}{2} \times D =$ *wha*. Por tanto, P está representado por el área del triángulo, *nbo*.

Con D en metros; si *y* = 1 metro, P en kilogramos = 500 D².

La presión **sobre una parte** *ed*, está representada por la presión sobre el trapezoide *ds* y se encuentra así :

Presión total en *ed* = presión total en *nd* — presión total en *ne*.

*Obs. del T.* — Para reemplazar las del autor damos la siguiente tabla de la presión total en gramos ejercida contra un **plano vertical** de 1 cent de ancho introducido desde la superficie del agua hasta las profundidades que indica la primera columna.

La presión total es igual á la mitad del cuad de la profundidad.

| Profd. en centímt. | Presión total en grams. | Profd. en centímt. | Presión total en grams. | Profd. en centímt. | Presión total en grams. | Profd. en centímt. | Presión total en grams. |
|---|---|---|---|---|---|---|---|
| 1 | .5 | 17 | 144.5 | 33 | 544.5 | 49 | 1200.5 |
| 2 | 2 | 18 | 162 | 34 | 578 | 50 | 1250 |
| 3 | 4.5 | 19 | 180.5 | 35 | 612.5 | 51 | 1300.5 |
| 4 | 8 | 20 | 200 | 36 | 648 | 52 | 1352 |
| 5 | 12.5 | 21 | 220.5 | 37 | 684.5 | 53 | 1404.5 |
| 6 | 18 | 22 | 242 | 38 | 722 | 54 | 1458 |
| 7 | 24.5 | 23 | 264.5 | 39 | 760.5 | 55 | 1512.5 |
| 8 | 32 | 24 | 288 | 40 | 800 | 60 | 1800 |
| 9 | 40.5 | 25 | 312.5 | 41 | 840.5 | 65 | 2122.5 |
| 10 | 50 | 26 | 338 | 42 | 882 | 70 | 2450 |
| 11 | 60.5 | 27 | 364.5 | 43 | 924.5 | 75 | 2812.5 |
| 12 | 72 | 28 | 392 | 44 | 968 | 80 | 3200 |
| 13 | 84.5 | 29 | 420.5 | 45 | 1012.5 | 85 | 3612.5 |
| 14 | 98 | 30 | 450 | 46 | 1058 | 90 | 4050 |
| 15 | 112.5 | 31 | 480.5 | 47 | 1104.5 | 95 | 4512.5 |
| 16 | 128 | 32 | 512 | 48 | 1152 | 100 | 5000 |

La presión total en kilogramos (para $y=1$ m) es igual al cuadrado de la profundidad en metros, multiplicado por 500. $P=500\ D^2$.

## TIEMPO

60 segundos, $\overset{*}{\prime}$ marcados $s=1$ minuto.
60 minutos, $\overset{\dagger}{\prime}$ — $m=3{,}600$ segundos.
24 horas, — $h=1$ día $=1{,}440$ m $=86{,}400$ s.
7 días, — $d=1$ semana $=168$ h $=10{,}080$ m.

| Arco. | Tiempo. |
|---|---|
| $1^o=4$ | minutos. |
| $1'=4$ | segundos. |
| $1'=$ | .066 segundos. |

| Tiempo. | Arco. |
|---|---|
| 24 horas | $=360^o$ |
| 1 hora | $=15^o$ |
| 1 minuto | $=0^o15'$ |
| 1 segundo | $=0^o0'15''$ |

**Métodos para calcular el tiempo.** Los astrónomos distinguen el tiempo solar medio, el tiempo solar verdadero ó aparente y el tiempo sideral.

Para un meridiano normal (pag 270) el tiempo solar medio es el tiempo que marcan los relojes. Para otro punto no situado en el meridiano normal, el tiempo **normal** es el tiempo solar medio local del meridiano adoptado como normal para dicho punto; y el tiempo *local*=al tiempo en el meridiano normal *más* la corrección por longitud de ese meridiano si el lugar está situado al *este* del meridiano y viceversa. Para el valor de esta corrección véase la segunda tabla arriba. **Un día solar verdadero ó aparente** es el tiempo transcurrido entre dos culminaciones sucesivas del sol por el meridiano de un mismo lugar; pero como estos intervalos son desiguales, no se corresponden con el movimiento uniforme de los relojes. Se supone un sol ficticio llamado « sol medio », moviéndose en el ecuador celeste con movimiento uniforme de tal manera que el intervalo entre sus culminaciones sea constante. Este intervalo se llama día solar medio y es el término

---

*El segundo se dividía antes en 60 partes iguales llamadas *terceros* (marcados $''$), pero ahora se lo divide por el sistema decimal.

† La antigua y confusa práctica de designar los minutos y segundos y terceros de tiempo así: $'$, $''$, $'''$, ya no está en boga. Ahora los días, horas, minutos y segundos se designan con las letras *d*, *h*, *m*, *s*, respectivamente; así: 2d (2 días), 20h (20 horas), 48m (48 minutos), 53s (53 segundos), y los símbolos $'$ y $''$ para los minutos y segundos *de arco*.

medio de todos los días solares *aparentes* en un año. El tiempo medio y el aparente concuerdan cuatro veces en el año, á saber : hacia mediados de abril y de junio, en septiembre 1 y diciembre 24. El sol está á veces « retardado » y á veces « adelantado » respecto al sol medio. En invierno está « retardado » y el máximo es hacia febrero 11, que pasa por el meridiano como 14 m 28 s *después* del medio día con respecto á cualquier reloj correcto. El sol está « adelantado » respecto á los relojes en mayo y después llegando á un máximum como de 16 m 20 s hacia noviembre 2.

La diferencia entre el día solar verdadero y el día solar medio se llama **ecuación del tiempo**. Se la encuentra en el Almanaque Náutico (ó en el Conocimiento de los Tiempos) ó aproximadamente tomando el término medio entre la salida y puesta del sol, dada por casi todos los almanaques.

Así como se mide el tiempo solar, por el movimiento aparente, diario del *sol*, así se mide el tiempo *sideral* por el de las estrellas fijas ó, hablando con más precisión, por el movimiento del equinoccio de primavera que es el punto en que el sol corta el ecuador en esa época.

**Un día sideral** es el intervalo de tiempo transcurrido entre dos pasos sucesivos del equinoccio de primavera (ó prácticamente de cualquier estrella) por el meridiano de un lugar. Es prácticamente el tiempo requerido para una revolución completa de la tierra alrededor de su eje. El día sideral es de 23 h, 56 m, 4.09 s, de día solar medio. Con otras palabras, una estrella aparece en un punto determinado del cielo 3 m, 55.91 s, antes de la hora en que apareció la anterior en el mismo punto midiendo el tiempo en un buen reloj. Por tanto, hay un día más sideral en un año que días solares medios.

El día sideral, como el solar, se divide en 24 horas y las horas siderales son por tanto más cortas que las solares en la misma proporción que los respectivos días. Se cuentan de 0 á 24 comenzando por el instante en que el equinoccio de primavera pasa por el meridiano.

**El día civil** (=24 horas de los relojes ó de tiempo solar medio) comienza á media noche y **el día solar astronómico** al mediodía del día civil de la misma fecha. Así, para un meridiano normal, el jueves, mayo 9, á las 2 A. M. tiempo civil, es miércoles mayo 8, 14 h tiempo astronómico; pero jueves mayo 9, 2 P. M., tiempo civil, es jueves mayo 9, 2 h tiempo astronómico.

**El mes civil** es el mes ordinario y arbitrario de los almanaques, que varía entre 28 y 31 días solares medios.

**El mes sideral** es el tiempo en que la Luna hace, con referencia á las estrellas, una revolución completa y su duración media en tiempo solar medio es como de 27 d, 7 h, 43 m, 12 s.

**El mes lunar** es el tiempo transcurrido entre dos lunas nuevas sucesivas; su duración media es como de 29 d, 12 h, 44 m, 3 s.

**El año natural ó tropical** es el tiempo transcurrido entre dos pasos sucesivos de la Tierra por un mismo equinoccio; su duración media en tiempo solar medio es ahora como de 365 d, 5 h, 48 m, 49 s.

**El año sideral** es el tiempo en que la Tierra describe su órbita completa respecto á las estrellas. Su duración media en tiempo solar medio es como 365 d 6 h, 9 m, 10 s.

**El año civil** es el arbitrario ó convencional y variable del tiempo comprendido entre el 1.º de enero y el 31 de diciembre, inclusives. Contiene generalmente 365 días solares medios de 24 horas; pero los años cuyos números son divisibles por 4, contienen 366 y se llaman **bisiestos**. Se exceptúan los años que terminan en dos ceros (00) y que no son divisibles por **400**. Estos no son bisiestos.

**Arreglo de un reloj por las estrellas.** El autor, después de haber arreglado su cronómetro durante un año por este método solamente, encontró diferencias de muy pocos segundos, con el tiempo calculado por cuidadosas observaciones solares. Escójase una ventana que vea hacia el **oeste** si es posible y que domine la vista de un caballete de techo ú otra línea horizontal fija, con preferencia hacia los 40º de altura sobre el horizonte, para evitar las perturbaciones debidas á la refracción, y distante 20 ms ó más. Anótese la hora en que cualquier estrella fija, brillante (no un planeta), pase por el alineamiento entre el techo y cualquiera línea fija y horizontal en el marco de la ventana, como por ejemplo un alfiler colocado en el marco. El punto de mira en la ventana, y el reloj deben estar iluminados. La estrella pasará cada noche por la línea dicha 3 m, 55.91 s más temprano que la anterior. Las estrellas próximas al Ecuador se mueven más rápidamente y son por tanto las mejores para estas observaciones. Si la primera observación se hace con una estrella hacia la media noche, esta misma estrella

servirá durante 3 meses, al fin de los cuales pasará ya con la luz del día. Antes que esto suceda, transfiérase el tiempo á otra estrella que salga más tarde. Formando tablas de observaciones durante el año con una media docena de estrellas que se sigan á intervalos de tiempo más ó menos iguales, se tendrá un regulador ó guía para regularizar la marcha de los relojes en cualquier noche clara. Haciendo observaciones el autor con dos de los mejores **cronómetros**, encontró variaciones de 3 á 8 segundos por día.

Un hombre normal da **dos pasos** (uno á la derecha, otro á la izquierda) **por segundo**. Por esto, la música marcial tiene un segundo por medida ó compás. Los relojes modernos dan cinco golpes (tic) por segundo, y los de pared, uno, dos ó cuatro.

## MODELO DE HORA DE LOS FERROCARRILES, ADOPTADO EN 1883*

La disposición siguiente, adoptada acerca de la hora modelo, fué recomendada por las Convenciones generales de la hora de los ferrocarriles de los E. U. y del Canadá, reunidas respectivamente en San Luis, Mo; en Nueva York en abril de 1883, y en Chicago Ill, y Nueva York en octubre de 1883, puesto en vigencia en casi todos los ferrocarriles de los E. U. y Canadá el 18 de noviembre de 1883. La mayor parte de las principales ciudades de los E. U. han hecho que sus respectivas horas locales correspondan con ella. Este sistema fué propuesto par W. F. Allen, Secretario de la « Convenciones del Tiempo » (« Time Conventions »); y su adopción fué debida en gran parte á sus esfuerzos. Nosotros debemos á Allen los documentos de donde se ha extractado lo siguiente. Cinco modelos de hora, ó cinco « horas » han sido adoptados por los E. U. y Canadá. Éstas son respectivamente la hora media de los meridianos 60, 75, 90, 105 y 120 al oeste de Greenwich (Inglaterra). Como cada uno de estos meridianos, en el orden anterior está 15° al oeste del que le precede, tiene una hora de atraso. Así, cuando es medio día en el meridiano 90, es la 1 P. M. en el 75, y las 11 A. M. en el 105. La tabla siguiente da el nombre adoptado de la hora modelo de cada meridiano y los colores convencionales elegidos y aceptados uniformemente por Allen, con el objeto de consignarlos juntamente con la hora y su tiempo, etc., en los mapas publicados bajo sus auspicios.

| Longitud al oeste de Greenwich. | Nombre de la hora modelo. | Color convencional, |
|---|---|---|
| 60° | Intercolonial. | Castaño. |
| 75° | Oriental. | Rojo. |
| 90° | Central. | Azul. |
| 105° | Montaña. | Verde. |
| 120° | Pacífico. | Amarillo. |

Teóricamente, se puede decir que cada meridiano da la hora para una faja de terreno de 15° de ancho, y con el meridiano por centro. Así, en el meridiano en el cual se supone que tiene lugar el cambio de hora de dos meridianos modelos, está situado en el medio de ellos. Pero no sería práctico para los ferrocarriles el uso de una línea imaginaria al pasar de una hora modelo á otra. Los cambios se hacen en las estaciones principales que constituyen el término de dos ó más líneas; ó en el caso de las grandes vías del Pacífico, al final de las secciones. Hasta donde se ha podido, en la práctica, los puntos en los cuales se habían efectuado cambios previos de hora, fueron elegidos por puntos de cambio bajo el nuevo sistema. *Detroit, Michigán; Pittsburgh, Pensylvania : Wheeling* y *Parkersburg, W. Va*, y *Augusta, Ga*, aun cuando no están situados sobre el mismo meridiano, son puntos de cambio entre los modelos de hora *orientales* y *centrales*. Un tren que llega á Pittsburg del Este á mediodía, y que sale para el Oeste 10 minutos después de su llegada, sale (según las indicaciones de su itinerario y reloj del conductor) no á las 12 h y 10 m, sino á las 11 h y 10.

La necesidad de efectuar cambios de hora en los puntos principales, en lugar

* *N. del T.* — Aunque esto no tiene importancia sino para los E. U., lo hemos dejado porque da muy clara idea de lo que puede hacerse en otras naciones.

de hacerlo en el meridiano verdadero, exige también alguna modificación de la hora ó de sus colores convencionales en el mapa. Así, en la mayor parte de las vías entre Búffalo y Detroit, al *norte* del lago Erie rige la hora « oriental » ó « roja »; mientras que en las del *sur* del lago, entre Búffalo y Toledo, inmediata y directamente opuestas al sur de ellos, rige la hora « central » ó « azul ».

Si los cambios de hora fueran hechos en los meridianos intermedios entre los meridianos modelos, no necesitaría ninguna ciudad variar su hora en más de 30 m. Como se hace actualmente, tienen que efectuarse mayores cambios en algunos puntos. De este modo, la hora modelo en Detroit tiene 32 minutos de adelanto, y en Savannah 36 minutos de atraso, con respecto al tiempo medio local.

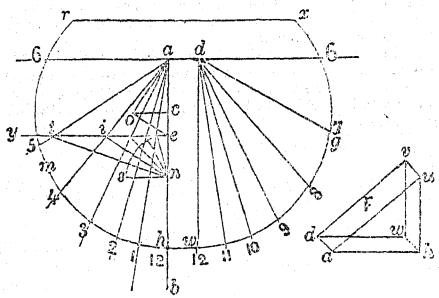
En la mayor parte de los casos se hacían los cambios de hora en los ferrocarriles adelantando ó atrasando los relojes el número necesario de minutos, sin hacer modificación alguna en sus itinerarios locales.

Halifax y algunas ciudades adyacentes usan la hora del meridiano sexagésimo por ser el más cercano; pero los *ferrocarriles* del mismo distrito han adoptado el meridiano 75 ú hora « oriental »; de modo que para los usos del ferrocarril, no se ha puesto en ejecución la hora intercolonial.

En 1873 habían 71 modelos de hora en uso en los ferrocarriles de los Estados Unidos y el Canadá. Para la época de la adopción de este sistema, este número había sido reducido á 53. Por su adopción, el número disminuyó á 5, ó practicamente, á 4, debido á la adopción de la hora « oriental » para las vías intercoloniales, como se ha explicado antes.

# GNOMÓNICA

**Para hacer un reloj de sol horizontal** trácese una línea *ab;* y en ángulo recto á ella trácese 66. Desde un punto conveniente *c*, en *ab*, trácese la perpendicular *co*. Hágase el ángulo *cao* igual á la latitud del lugar; también el ángulo *coe* igual á la misma latitud; trácese *oe*. Hágase *en* igual á *oe*, y desde *n* como centro. con el radio *en* descríbase un cuadrante *es*, y divídase éste en 6 partes iguales. Trácese *ey* paralela á 66; y desde *n* por los 5 puntos del cuadrante, trácense líneas



*nt, ni*, etc., que terminen en *ey*. Desde *a* trácense líneas *a*5, *a*4, etc., que pasen por *t*, *i*, etc. Desde cualquier punto conveniente *c*, descríbase un arco *rmh*, especie de límite ó borde de la mitad del reloj.

Ahora pueden borrarse todas las líneas, excepto las horarias *a*6, *a*5, *a*4, etc, hasta *a*12 ó *ah*, á menos que, como ocurre generalmente, haya que dividir el reloj en cuartos de hora. En este caso cada una de las divisiones del cuadrante *es* debe ser subdividida en cuatro partes iguales; y las líneas trazadas desde *n*, por los puntos de subdivisión terminarlas en *ey*. Las líneas de cuarto de hora deben ser trazadas desde *a* como lo fueron las líneas horarias. Pueden hacerse subdivisiones de 5 minutos de la misma manera; pero éstas, así como los minutos, pueden marcarse al ojo, alrededor del borde. Para un reloj ordinario úsese como 8 ó 10 veces el tamaño de la figura. Para trazar la otra mitad de la figura, hágase *ad* igual al espesor que se le quiere dar al estilo, del reloj; y trácese *d*12 paralela é igual á *a*12, y el arco *xgw* precisamente semejante al arco *rmh*. Entre *x* y *w* en el arco *xgw* tómense divisiones iguales á las del arco *rmh*, y numérense las horas como en la figura. El estilo F de metal ó piedra (la madera es muy fácil de torcerse) será triangular, su grueso igual en toda su extensión á *ad*, ó *hw;* su base debe cubrir el espacio *adhw;* su extremo debe estar en *ad;* y su altura *hu*, perpendicular á *hw*, debe ser tal que las líneas *vd*, *ua*, trazadas desde su parte superior hacia *ad*, hagan los ángulos *uah*, *vdw*, iguales cada uno á la latitud del lugar. Su espesor, si es de metal, puede ser de (3 á 6 mm); y si es de piedra 1 ó 2 pulgs (25 á 50 mm) ó más, según el tamaño del reloj. Generalmente, por elegancia, la parte de atrás *huvw* del estilo es hueca interiormente. Los bordes superiores *ua*, *vd* que producen las sombras, deben ser afilados y rectos. El reloj debe fijarse horizontal, ó perfectamente á nivel; *ha* y *dw* deben ser colocados exactamente de norte á sur; *ad* al sur, y *hw* al norte. El cuadrante indica solamente horas solares ó tiempo solar; pero se puede conseguir la hora de los relojes por medio del « retardo ó adelanto del sol» (ecuación del tiempo). Si, según el almanaque, el sol está adelantado 5 minutos, etc., el cuadrante estará lo mismo, y para que el reloj esté correcto debe estar 5 minutos más atrasado que él y viceversa.

**Para hacer un reloj de sol vertical.** Procédase como se ha indicado arriba excepto que los ángulos *cao* y *coe* del trazado, y el ángulo *uah* ó *vdw*, del estilo,

deben ser iguales á la *co*-latitud del lugar (=90°—latitud) y las horas deben numerarse en sentido inverso á las de la figura anterior, esto es : desde *h* hacia *y*, los números 12, 11, 10, 9, 8, 7 y, desde *w* hacia *g* los 12, 1, 2, 3, 4, 5. La estera ó muestra del cuadrante debe ser colocada verticalmente, en la posición que da la figura con el frente exactamente al sur y *ah* y *dw* verticales.

# MEDIDA DE TABLAS DE MADERA*

**Advertencia sobre la siguiente tabla.** Esta tabla suministra la medida ó el número de pies cuadrados de tabla que contiene el pie corrido de piezas de madera hasta de 12 pulgs de espesor por 24 pulgs de ancho; pero es fácil calcular el número de pies contenidos en piezas de mayores dimensiones. Por ej. : el número de pies contenidos en una pieza de 19×22 será el doble del de una de 19×11 ó sean (véase la tabla) 17.42×2=34.84 pies cuadrados de tabla; el de una de $19^1/_2 \times 22$ será el de una de $10^1/_2 \times 22$ sumado con el de una de 9×22 ó sean 18.79+16.50= =35.29. Se entiende aquí por un pie cuadrado de tabla ó simplemente un pie de tabla, una tabla de 1 pie en cuadro por 1 pulgada de espesor ó sean 144 pulgadas cúbicas. Por consiguiente, 1 pie cúb=á 12 pies de tabla.

* *N. del T.* — Aunque estas tablas están en sistema inglés, es tan frecuente en las compras y empleo de las maderas el uso de aquellas medidas, que hemos creído conveniente dejarlas.
El m cúb contiene 423.777 pies de tabla.
Un pie de tabla = 2359.72 cm cúb = 0.00235972 m cúb.

## Medida de tablas de madera.

Número de pies cuadrados de tabla contenidos en un pie lineal de madera en piezas de diferentes dimensiones (Original.)
1,000 pies de tabla=83 1/3 pies cúbs.

# LEVANTAMIENTO DE PLANOS

Al levantar una porción de terreno, los lados que formen el perímetro se designan por números en el orden que se van levantando. En cada lado el extremo que se encuentra primero en el curso del levantamiento, puede denominarse *extremo inmediato*, y el otro, *extremo distante*. El número de cada lado se coloca en el extremo distante. Así, fig. 1, suponiendo que el levantamiento comienza en el vértice **6** y continúa en el sentido de las flechas, el primer lado es 6, 1; y su número se coloca en el extremo distante 1 y así de los demás. Sea N-S una meridiana, es decir, una línea norte sur; y E-O una línea este oeste. En un lado cualquiera que se incline hacia el Norte, ya sea hacia el propio Norte, ó hacia el noreste, como los lados 5 y 1, la distancia del extremo inmediato al distante, tomada en dirección norte, se llama

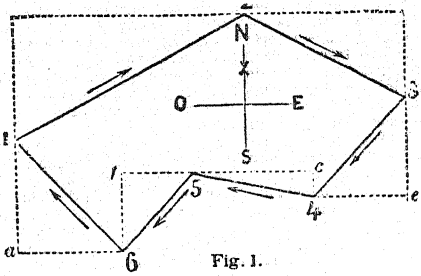

Fig. 1.

latitud norte; así, *a*1 es la dif de lat N del lado 1; 1*b* la dif de lat N del lado 2; 4*c* la del lado 5. De igual manera, si un lado cualquiera se dirige hacia el Sur sea exactamente en dirección Sur, ó con desviación al Este, como el lado 3, ó al Oeste, como los lados 4 y 6, la dist medida en la dirección Sur, del extremo inmediato al distante, se llama dif de lat S de dicho lado; así, *d*3 es la dif de lat S del lado 3; 3*e*, la del lado 4; *f*6, la del lado 6. Ambas dif están comprendidas bajo el término general de *Diferencias de latitud* de un lado, ó como se dice más comúnmente, pero erróneamente, su *latitud*. La dist entre los extremos de un lado cuando éste se inclina al Este ó al Oeste, se llama, de igual manera, dif de meridiano al Este ó al Oeste según el caso, de modo que 6*a* es la dif de mer O del lado 1; 5*f*, la del lado 6; *c*5, la del 5; *e*4 la del 4, y *b*2 la dif de mer E del lado 2; 2*d* la del lado 3. Cuando se habla sólo de la *diferencia de meridiano* (*departure*) de un lado, se entiende, indiferentemente al Este ó al Oeste.

No se puede llegar á una completa exactitud en las operaciones que tienen por objeto la medida de ángulos y distancias *. Hecha una operación con una exactitud suficiente, no se puede obtener mayor precisión sino haciendo mayores gastos. El autor cree que las diferencias en la precisión con que se efectúa un buen levantamiento, viene á traducirse siempre en dólares y céntimos. En la compra y venta de porciones de terreno, de labranzas, etc., una dif de 1 en 200 en la superficie, y de consiguiente en el precio, es muy probable que nunca sea motivo á que se desista del negocio, y basados en esto suponemos que una mensura hecha

* Una cadena de 100 pies de largo, por el solo cambio de temperatura del invierno al verano puede producir un error de 5 pies en la medida de una milla en longitud. En la medida de superficies será de 1 en 533 **.

** *N. del T.*— No sabemos por qué fija la longitud de la cadena para determinar el valor del error en longitud de 5 pies por milla, á causa de la dilatación ó contracción producidas por los cambios de temperatura extremos entre el invierno y el verano, toda vez que esto depende de la naturaleza del metal que la forma (que aunque no lo indica, lo suponemos de acero como se usa generalmente), pero no de la longitud de la cadena, pues cualquiera que ella sea producirá siempre el mismo error por milla. Hablando en metros resultará un error por dicha causa y con cadenas del metal que generalmente se usa de .95 m por cada kilómetro que se mida. El error en superficie será siempre de 1 en 533 cualquiera que sea la unidad que se adopte.

entre estos límites de error, merece generalmente que se la considere como exacta. No hay dificultad en llegar á este límite de exactitud, y cuando no se logra, es porque se ha trabajado mal. Muchas circunstancias se combinan para producir errores de poca significación y absolutamente inevitables, los cuales aparecen al trasladar al papel las anotaciones tomadas en el terreno, y desde luego afectan al plano y al cálculo de la superficie. Entonces hacemos lo que comúnmente se llama *corregir* los errores; pero que en realidad es simplemente disimularlos. Esto sucederá siempre por más esmero científico que se haya tenido en el procedimiento. Dos métodos se usan con este fin, ambos basados en el mismo principio, uno de ellos, mecánico, por medio del trazado; el otro, por el cálculo, más exacto, pero mucho más enojoso. Describiremos ambos métodos; pero haremos la observación de que proporcionando una escala para el plano como lo indicamos en seguida, el método mecánico empleado por un dibujante hábil es bastante exacto para los usos ordinarios. Súmense todos los lados en pies y divídase la suma por el número de lados para obtener su longitud media. Divídase esta longitud media por 8; el cociente será la escala propia en pies por pulgada. En otras palabras, representemos por 8 pulgadas cada lado medio †*. Suponemos que ningún ingeniero considere exacta la medida de los ángulos con una aproximación de un cuarto de grado, que es la práctica usual entre los agrimensores. Pueden medirse por medio del tránsito de ingeniero, actualmente de uso universal en nuestras obras públicas, con uno ó dos minutos de aproximación, y siendo mucho más exactos que los rumbos tomados con la brújula (los cuales no pueden llevarse á tanta aproximación, y están por otra parte sujetos á muchas causas de errores), sirven para corregir éstos en la oficina.

La anotación de los rumbos, sin embargo, no debe limitarse á cuartos de grado, deben apreciarse los minutos del ángulo tan próximamente como sea posible al observador; también debe tomarse el rumbo á la espalda en cada vértice, como comprobación adicional. Es bueno, al tomar las indicaciones de la brújula, adoptar como regla que se dirija siempre el norte de la caja de la brújula hacia el objeto cuyo ángulo se va á tomar; y hacer la lectura desde la punta N de la aguja. Los que usen indiferentemente el N y el S de la caja de la aguja estarán muy expuestos á cometer errores. También es mejor medir el ángulo más pequeño marcado con líneas de puntos, fig. 2) en los vértices, sea exterior como en el

---

† *N. del T.* — En el sistema métrico, procédase así: Súmense todos los lados medidos en metros, y divídase la suma por el número de lados para obtener su longitud media. Multiplíquese ésta por 5 y el producto será el dominador de la escala cuyo numerador es 1. Ej.: supongamos que la suma de los lados da 3660 metros y que son 10 lados; $\frac{3660}{10} = 366$ metros será el largo medio de ellos y multiplicado por $5 = 366 \times 5 = 1830$ da el denominador de la escala, que será $\frac{1}{1830}$. Siempre se escogerá para escala una fracción próxima más adecuada. En este caso $\frac{1}{2000}$, por ejemplo.

★Los jóvenes ayudantes deberían practicar delineando ó trazando con datos perfectamente exactos. Este es el único modo de aprender lo que se entiende por trabajo exacto. El transportador semicircular debe ser de 9 á 12 pulgs de diám (25 á 30 cm) y graduado á 10 minutos. La regla y escuadra deben ser de metal; preferimos la plata alemana que no se oxida como el acero, y deben estar hechas con *escrupulosa exactitud* por un hábil fabricante de instrumentos. Una aguja muy fina, con cabeza de lacre manejada verticalmente, debe emplearse para marcar las dist y los ángs, y el ojo del dibujante debe colocarse directamente sobre ella. El lápiz debe ser duro (Faber nº 4 es bueno para transportar) y conservarle la punta aguda frotándola en una lima fina después de tajar la madera con la navaja. La escala debe ser por lo menos de la longitud del lado más largo del plano, y deberá trazársela en el borde de una tira del mismo papel en que se dibuja. Esto evitará, en gran parte, los errores que nacen por la contracción y dilatación del papel. Desgraciadamente, un pliego de papel no se contrae y dilata en la misma proporción, á lo largo que al través, impidiendo así que la escala hecha en la tira de papel, como lo hemos indicado, proporcione un medio eficaz de corregir el error. En los planos de levantamientos comunes de granjas, haciendas, etc., pueden despreciarse los errores de esta procedencia. Para tales planos, como han de transportarse, dividirse y calcularse en un tiempo demasiado corto para admitir cambios apreciables, las escalas ordinarias de madera, marfil ó metal, pueden emplearse; pero no se pueden obtener con ellas resultados satisfactoriamente exactos en planos que exijan muchos días, y más si el aire está alternativamente húmedo y seco, ó sujeto á variaciones considerables de temperatura. El papel llamado de *pergamino* (parchment) es peor á este respecto que el buen papel de dibujo.

Con las precedentes precauciones, se puede hacer un dibujo con tanta exactitud como a que se alcanza en las operaciones del terreno.

vértice 5, ó interior como en todos los otros; porque así es siempre menor que 180°; de modo que hay menos peligro, de hacer una lectura equivocada, que cuando excede de 180°, esto es, en el caso de que el tránsito esté graduado á un lado y á otro de 0° á 180°; si tiene una sola graduación de 0° á 360°, la precaución es

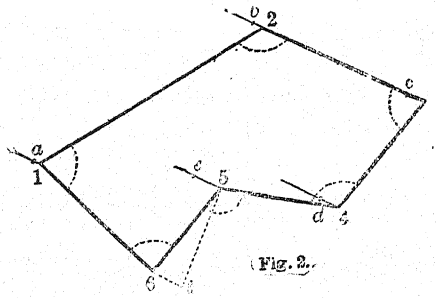

Fig. 2.

inútil. Cuando el ángulo exterior es pequeño, réstese de 360° para obtener el interior.

Suponiendo concluído el trabajo sobre el terreno, y que deseamos un plano que nos dé la superficie dividiéndola en triángulos (cuyas bases y alturas puedan medirse á la escala y sus áreas calcularse una por una) debemos desde luego transportar las anotaciones del terreno, sea usando los *ángulos* ó calculando primero las orientaciones en un solo sentido, por medio de los ángulos, y luego aplicándolas. El último modo es preferible, porque en el primero el transportador puede ser movido para cada ángulo, mientras que en el último permanece fijo en tanto que se marcan los rumbos. Cada movimiento de aquél aumenta la probabilidad de error. El modo de corregir los errores se explica en la página siguiente.

En uno ú otro caso, el polígono transportado de seguro que no cerrará exactamente, no sólo como consecuencia de los errores por las operaciones del terreno, sino también al transportarlas al dibujo. Así, el último lado, n.° 6, fig. 2, en lugar, de cerrar en el vértice 6, terminará en cualquiera otra parte, por ejemplo en *t*, siendo la distancia 6 *t* el error correspondiente, el cual, sin embargo, tal como está representando en la fig. 2, es más de diez veces mayor en relación al tamaño del plano, que lo que se admite en la práctica. Para distribuir este error, trácese por cada vértice una pequeña línea paralela á *t* 6 y siempre en la dirección *t* 6. Súmense todos los lados, y mídase *t* 6 en la escala del plano. Luego empezando en el vértice 1, digamos :

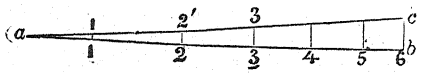
$$\text{Suma de todos los lados} : \text{Error total de cierre } t\,6 :: \text{Lado 1} : \text{Error corresp. al lado 1.}$$

Llévese este error de 1 á *a*. Entonces en el vértice 2 tenemos :

$$\text{Suma de todos los lados} : \text{Error total de cierre } t\ 6 :: \text{Suma de los lados 1 y 2} : \text{Error corresp. al lado 2.}$$

Dicho error colóquese de 2 á *b*, y así en cada vértice; siempre usando, como tercer término, la suma de los lados entre el punto de que se trata y el error de cierre dado. Finalmente, únanse *a*, *b*, *c*, *d*, *e*, 6, y el alineamiento está concluído. La corrección ha cambiado evidentemente la longitud de cada lado, alargando á unos y acortando á otros. También han cambiado los ángulos. Las nuevas longitudes y los nuevos ángulos pueden con exactitud tolerable hallarse por medio de la escala y el transportador, y ser marcados en el trazado en lugar de los anteriores. Cuando el plano tiene muchos lados, el cálculo del error para cada uno de ellos se hace fastidioso, y como en una mensura bien practicada y bien transportada, el error total es muy pequeño (no excederá de $\frac{1}{400}$ del perímetro), puede entonces

dividirse entre los lados, simplemente distribuyendo $^1/_4$, $^1/_2$ y $^3/_4$ del error en los vértices situados á distancia más ó menos de $^1/_4$, $^1/_2$ y $^3/_4$ del contorno del perímetro; y en los vértices intermedios, distribúyaselos al ojo. Puede también evitarse todo cálculo así: trazando una línea *ab* de longitud igual á la longitud unida de todos los lados, y dividiéndola en dist *a* 1, 1 2, etc., iguales á los lados res-



pectivos. Hágase *bc* igual al error total, únase *ac* y trácese 1.1'; 2,2', etc., que darán el error en cada vértice.

Cuando el dibujo está terminado así, debe dividirse con líneas finas de lápiz en triángulos cuyas bases y alturas se miden por la escala con el fin de calcular el área. Poniendo cuidado, tanto en el levantamiento como en el trazado, el error no excederá de $^1/_{200}$ del área verdadera. Para evitar equivocaciones deben trazarse y calcularse, por lo menos, dos series distintas de triángulos, y si el área que resulta difiere en más de $^1/_{200}$, es señal de que no han sido preparadas con suficiente cuidado.

El error por el cual no cierra el perímetro debido á la imperfección de trabajo sobre el terreno debe calcularse exactamente como lo indicamos, y hacerse constar en el papel antes de comenzar el dibujo del plano, logrando así una prueba perfecta de la exactitud del dibujo, que si se hace correctamente, no cerrará en el punto de partida, sino en el indicado por el error. El cálculo de éste, con un poco de más trabajo, suministra igualmente el modo de distribuirlo dentro de los diferentes lados y la manera de trazar desde luego el plano correctamente sin el uso del transportador, poniéndonos en capacidad de hacer con más certeza las medidas subsiguientes y el cálculo de los triángulos.

Describiremos ahora este procedimiento; pero recomendamos que aun cuando se emplee, especialmente en levantamientos complicados, se haga primero un croquis, y se corrija por medio del primer método mecánico á que hemos hecho alusión. Se verá que es de gran utilidad al usar el método del cálculo. Al mismo tiempo que da práctica para evitar á la simple vista equivocaciones desagradables, que de otro modo suelen ocurrir, sus principios son por demás sencillos y fácilmente se recuerdan una vez comprendidos. Los continuos cambios en las direcciones de los lados, nos harán, si no se tiene gran cuidado, tomar diferencias de lat. N por dif. de lat S y dif de mer al E por O.

Suponemos, pues, que dicho croquis ha sido preparado, y que los ángulos, direcciones y distancias, figuran en él al lapiz como han sido tomadas del libro de memorias.

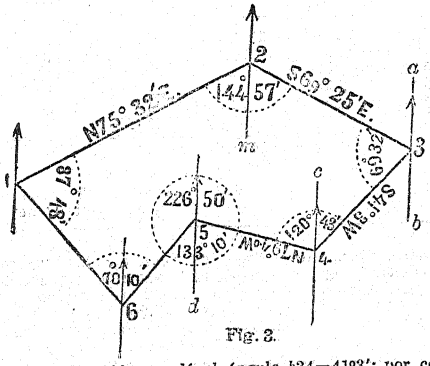
Súmense los ángulos interiores formados en todos los vértices; llámese esa suma *a*, multipliquese el número de lados por 180°, réstese del producto, 360°, si la diferencia es igual á la suma *a*, es prueba de que los ángulos han sido medidos correctamente *. Esto, sin embargo, ocurrirá rara vez, siempre habrá discrepancias; pero si el trabajo en el terreno ha sido ejecutado con regular cuidado, no excederán los errores de dos minutos, más ó menos, por cada ángulo. En este caso distribúyase el exceso por partes iguales entre todos los ángulos, sumando ó restando según sea el caso; excepto que corresponda á menos de dos minutos para cada ángulo, pues esto debe despreciarse en levantamientos ordinarios. Los ángulos corregidos pueden trazarse entonces con tinta en el plano y borrarse el trazado de lápiz. Supongamos los ángulos ya corregidos como se ven en la figura 3. Luego, por medio de estos ángulos corregidos, corríjanse también las direcciones; así: fig. 3. Escójase un lado (mientras más largo mejor). Sea el lado 2 el elegido, su orientación N 75°32' E, la supondremos correcta por ser tomada sobre el terreno. Trácese por sus extremos la meridiana y llévense paralelas á ella por los demás vértices del polígono. Ahora bien, siendo la dirección del lado 1, 2, N 75°32' E y necesitándose conocer la del lado 3, es claro que la dirección ú orientación inversa del primero desde el vértice 2, es S 75°32' O † y que por tanto el ángulo 1, 2, *m*, es de 75°32'. De consiguiente, si tomamos 75°32 del ángulo entero corregido 1, 2, 3, ó de 144°57',

---

* Porque la suma de los ángulos internos de un polígono es igual á tantas veces dos rectos como lados tiene menos 4 ángulos rectos ó 360°.

† *N. del T.* — En esta figura la letra W indica el Oeste (West).

la diferencia de 69°25′ será el ángulo *m*, 2, 3; por tanto la dirección del lado 3 debe ser S 69°25′ E. Para hallar la del lado 4, tenemos ahora el ángulo 2, 3, *a*, orientación inversa del lado 2, 3, también igual á 69°25′, y si agregamos este ángulo al entero corregido 2, 3, 4, ó á 69°32′, tendremos el ángulo *a*3, 4=69°25′+69°32′ =



138°57′, que restado de 180° nos dá el ángulo *b*34=41°3′; por consiguiente, la dirección del lado 4 debe ser S 41°3′ O.

Para la dirección de lado 5 tenemos ahora el ángulo 3, 4, *c*=41°3′, que restado del ángulo corregido 3, 4, 5 ó 120°43′ queda el ángulo *c*, 4, 5=79°40′; por tanto la dirección del lado 5 debe ser N 79°40′ O. En el vértice 5 para la dirección del lado 6, tenemos el ángulo 4, 5, *d*=79°40′ que tomados de 133°10′ queda el ángulo *d*5 6=53°30′; por consiguiente, la dirección del lado 5, 6 debe ser S 53°30′ O. Así en cada uno de los lados, sólo se necesita una observación cuidadosa para ver cómo deben aplicarse los diferentes ángulos en cada vértice.

Algunas veces se han dado reglas con este objeto; pero si no se usan frecuentemente, se olvidan pronto. El plano previamente preparado evita la necesidad de dichas reglas, tanto más cuanto que el principio del procedimento aludido se reduce únicamente á un asunto de simple vista y tiende en gran manera á impedir los errores provenientes de erradas direcciones, en tanto que el transportador revela inmediatamente cualquiera equivocación sería cometida en los ángulos, impidiendo así su propagación. Después de haber obtenido todas las direcciones corregidas, deben trazarse en el plano, en lugar de las tomadas en el terreno. Sin embargo, requerirán todavía una nueva corrección desde luego que estarán afectadas al cerrarse el polígono del error correspondiente.

Ahora procedamos al cálculo de este error, *t*6, fig. 2, el cual está basado en el principio de que en una medida correcta, las diferencias de latitud norte son iguales á las de latitud sur, y las diferencias de meridiano del este á las del oeste. Prepárese una tabla de siete columnas como se ve á continuación, y en las primeras tres columnas colóquense los números de los lados y sus direcciones corregidas : también las distancias ó longitudes de los lados según fueron medidas en el croquis, si se ha hecho uno, pero si no, según fueron medidas en el terreno. A saber

| Lado. | Dirección. | Dist. en m. | Diferencias de latitudes. | | Diferencias de meridianos. | |
|---|---|---|---|---|---|---|
| | | | N. | S. | E. | O. |
| 1 | N. 16° 40′ O. | 1060 | 1015.5 | | | 304. |
| 2 | N. 75° 32′ E. | 1202 | 300.3 | | 1163.9 | |
| 3 | S. 69° 25′ E. | 1110 | | 390.2 | 1039.2 | |
| 4 | S. 41° 3′ O. | 850 | | 641. | | 558.2 |
| 5 | N. 79° 40′ O. | 802 | 143.9 | | | 789. |
| 6 | S. 53° 30′ O. | 705 | | 419.3 | | 566.7 |
| | | | 1459.7 | 1450.5 | 2203.1 | 2217.9 |
| | | | 1450.5 | | | 2203.1 |
| | | | 9.2 | Error en lat. | Error en las dif. de mer. | 14.8 |

Búsquense ahora por medio de la Tabla de senos, etc., las proyecciones N, S, E, O, de los diferentes lados y colóquense en la que le corresponde de las cuatro columnas. Así: para el lado 1, que tiene 1,060 m con rumbo N 16 40 ; cos 16°40′ = .9580; sen 16 40′ = .2868. Entonces N = 1,060 × .9580; O = 1,060 × .2868 = 304 Procédase así con todos. Súmense las cuatro columnas; búsquese la diferencia entre las columnas N y S y entre las columnas E O. En este caso encontramos que las dif de lat N son 9.2 mayores que las dif de lat S y que las dif de mer O exceden en 14.8 á las del E. En otras palabras, hay un error al cerrar el polígono que haría que al transportar fielmente las primeras tres columnas se terminase 9.2 m hacia el N del punto de partida y con una desviación de 14.8 al O del mismo.

De modo que habiendo anotado este error sobre el papel antes de comenzar á transportar, habríamos tenido un medio de comprobar su exactitud; pero como se ha advertido anteriormente, un poquito de más trabajo nos facilita la división del error entre todos los lados y nos pone en disposición de trazar el plano de una vez correctamente.

Para distribuir los errores prepárese una tabla precisamente igual á la anterior con la excepción de que los espacios horizontales han de estar más separados, y en la cual se omiten las adiciones de las columnas N, S, E, O. Las adiciones de que hemos hecho mención se hacen inmediatamente después.

La nueva tabla es la inmediata siguiente.

**Observación.** La **orientación de una línea** en un extremo **no tiene exactamente el mismo valor angular** que la inversa en el otro extremo, la diferencia varía con la latitud y con el largo de la línea; pero no en la misma proporción. Sin embargo, la diferencia es generalmente tan pequeña, que no puede ser apreciada por la aguja. Según Gummere, alcanza sólo á $^{3}/_{4}$ de minuto en una milla (1,609 m), á la latitud de 40°; en latitudes más altas, es mayor, y menor en las más bajas, lo que se debe á que los meridianos ó líneas N-S no son verdaderamente paralelos entre sí, pues se cortan en los polos.

De aquí que **el único rumbo que puede seguirse en línea recta con toda exactitud** es la verdadera N-S, excepto en el Ecuador mismo donde una línea E-O es también una línea recta. Puede trazarse una verdadera E-O en cualquiera latitud, con bastante exactitud para los propósitos del agrimensor, así: habiendo obtenido primero, por medio de la estrella Polar, pág. 296, una verdadera N-S; en el punto de partida tómense 90° á contar de la N-S para obtener la verdadera dirección E-O en ese punto. Esta dirección E-O será tangente á la curva E-O del paralelo respectivo. Sígase esta tangente cuidadosamente y á intervalos (digamos al fin de cada milla) desviese desde ella (hacia el N si estamos en latitud N ó á la inversa si en latitud S) una distancia cuya longitud en pies sea igual á la que le corresponda según la latitud en los datos siguientes, multiplicando la desviación indicada abajo por el cuadrado de la distancia en millas desde el punto de partida. Estas dist marcarán puntos de la verdadera curva E-O.

**Latitud N ó S**

5° 10° 15° 20° 25° 30° 35° 40° 45° 50° 55° 60° 65°

**Desviación en pies para una milla á contar del punto de partida.**

.058 .118 .179 .243 .311 .385. 467 .559 .667 .795 .952 1.15 1.43

*N. del T.* — **Desviación en centímetros para un kilómetro á contar del punto de partida.**

| 5° | 10° | 15° | 20° | 25° | 30° | 35° | 40° | 45° | 50° | 55° | 60° | 65° |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 1.10 | 2.20 | 3.39 | 4.60 | 5.89 | 6.80 | 8.84 | 10.59 | 12.63 | 15.06 | 18.03 | 21.78 | 27.8 |

**Cualquiera desviación en pies** es=.6666×(dist total en millas)²×tang de la latitud.

*N. del T.* — Esta fórmula para el sistema métrico es así :

**Cualquiera desviación en metros**=.0782447×(dist total en kilómetros)²×tang de la latitud.

**Rumbo** es una línea cualquiera que corta al meridiano oblicuamente, es decir, que no es ni N-S ni E-O.

Ahora hemos encontrado por la tabla vieja que las difs de lat N y las difs de mer al oeste son demasiado largas y por consiguiente deben acortarse, mientras que las al S y al E deben alargarse; todo en las proporciones siguientes :

Suma de todos los lados : Cualquier lado dado :: Error total de lat ó dif de meridiano : Error de lat ó de dif de meridiano del lado dado.

Así, comenzando por la lat del lado 1 tendremos :

Suma de todos los lados. 5,729 : Lado 1 1,060 :: Error total de latitud 9.2 : Error de lat del lado 1. es decir 1.7.

Ahora, como la lat del lado 1 es Norte, debe ser acortada y viene á ser por consiguiente 1,015.5 — 1.7 = 1,013.8 como está en la nueva tabla.

También tenemos por dif de meridiano del lado 1.

Suma de todos los lados 5,729 : Lado 1 1,060 :: Error total en la dif de mer 14.8 : Error en la dif de mer del lado 1 ó sea 2.7.

Ahora bien, como la dif de meridiano del lado 1 es Oeste, debe acortarse; de consiguiente se convierte en 304 — 2.7 = 301.3 como figura fuera en la nueva tabla*

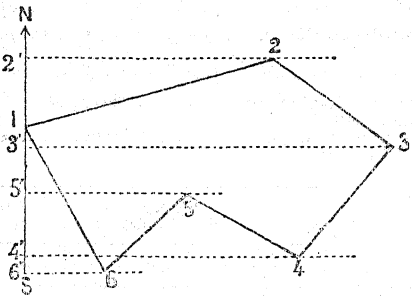

Fig. 4.

Procediendo así con cada lado obtendremos todas las lats y difs de meridianos correctas, como se ve en la nueva tabla donde están unidas á sus lados respectivos por medio de líneas de puntos; pero en la práctica es mejor tachar las originales cuando se ha terminado y probado el cálculo. Si sumamos ahora las 4 columnas corregidas N S E O, encontramos que las difs de lat N son=las difs de lat S y las difs de mer E=las difs de mer O, probando esto que está correcto el trabajo. Hay en verdad una discrepancia de .1 de m entre las difs de lat N y las difs de lat S; pero esto es debido á que hemos apreciado las correcciones con una sola cifra decimal y es demasiado pequeña para ser considerada. Ocurrirán algunas veces, por esta causa, discrepancias de 10 ó 12 cm, pero pueden ser despreciadas. Las lats y difs de meridiano corregidas deben evidentemente cambiar los rumbos y distancias de todos los lados; pero sin conocer ninguna de estas dos, podemos ahora transportar las mensuras por medio de sólo las lats y difs de meridiano corregidas. El sistema se explica evidentemente por sí mismo. Trácese primero una línea meridiana N-S, fig. 4, y sobre ella fíjese un punto 1 para representar el vértice extremo oeste* de la mensura.

Entonces desde el punto 1 indíquese con puntos en partes de la escala hacia el norte la distancia 1.2=la dif de lat norte corregida 298.4 del lado 2, tomada de la tabla última; desde 2′ hacia el sur indíquese del mismo modo la distancia 2′, 3′, dif de lat sur corregida 392 del lado 3; de 3′ hacia el sur la 3′, 4′, =dif en la lat sur 642.3 del lado 4; desde 4′ hacia el norte la 4′, 5′, =dif de lat norte 142.6 del lado 5; desde 5′ indíquese hacia el sur 5′, 6′, =dif. de lat sur del lado 6†. Entonces desde los puntos 2′, 3′, 4′, 5′, 6′, trácense líneas indefinidas con dirección hacia el este, es decir, en ángulos rectos á la meridiana. Hágase por la escala á 2′, 2=dif de mer corregida del lado 2, y únanse 1 y 2. Hágase 3′ 3=dif de mer del lado 2+dif de mer del lado 3, y únanse 2 y 3; hágase 4′, 4=3′, 3 — dif de mer del lado 4, y únanse 3 y 4; hágase 5′, 5=4′, 4 — dif de mer del lado 5, y únanse 4 y 5;

---

* El vértice del extremo este servirá también con una pequeña variación en la operación subsiguiente como se comprende á la simple vista.

† En lugar de indicar con puntos estas dif de lat norte y sur sucesivamente, será más correcto en la práctica, preparar primero una tabla demostrando á qué distancia está cada uno de los puntos 2′, 3′, etc. del punto 1 hacia el norte ó el sur. Habiendo hecho esto, los puntos pueden indicarse de aquel modo hacia el norte ó hacia el sur desde el punto 1, sin tener que mover la escala en cada vez y, además, con mayor exactitud. Dicha tabla ha sido ya formada. Ráyese como sigue, y en las primeras tres columnas colóquense los números de los lados (comenzando por el lado 2 extremo del lado 1, 2) y sus respectivas diferencias de latitudes norte y sur corregidas. La formación de la

hágase 6', 6=5', 5 — dif de mer del lado 6, y únanse 5 y 6 ‡, y finalmente únanse 6 y 1 y estará completo el polígono. Si no se requiere mucha exactitud, la superficie puede encontrarse por medio de triángulos; las direcciones por medio del trans-

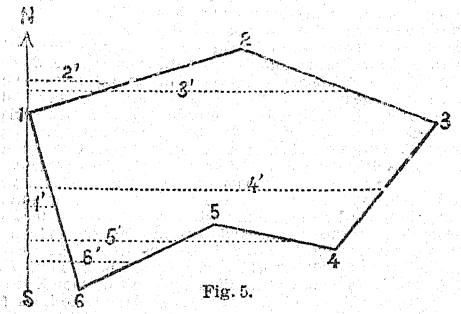

Fig. 5.

portador; y las longitudes de los lados por medio de la escala; todo con una aproximación suficiente para los fines ordinarios y quizá casi tan aproximada como por el cálculo, cuando como es costumbre los rumbos se toman con un cuarto de grado de aproximación. Hemos dicho ya que con una escala de pies por pulgadas $= \frac{\text{término medio de la longitud de los lados}}{8}$, el error en el área no excederá de $\frac{1}{200}$.

(*N. del T.* — Como dijimos también en el mismo párrafo en que el autor dió

---

columnas 4.ª y 5.ª por medio de la 3.ª y 4.ª se explica á la simple vista. La exactitud está probada por el resultado final que es 0.

| Lado. | Lat. N. | Lat. S. | Dist. N. ó S. desde el punto 1. | |
|---|---|---|---|---|
| | | | N. | S. |
| 2 | 298.4 | | 298.4 | |
| 3 | | 392. | | 93.6 |
| 4 | | 642.3 | | 735.9 |
| 5 | 142.6 | | | 593.3 |
| 6 | | 420.4 | | 1013.7 |
| 1 | 1013.8 | | 000.0 | 000.0 |

‡ Debería de antemano prepararse una tabla semejante para las distancias de los puntos, 2, 3, 4, etc. al este de la meridiana. Esta se hace de la misma manera; pero necesita una columna menos, pues todas las líneas están del mismo lado de la meridiana. Así, comenzando desde el punto 1 con el lado 2.

| Lado. | Dif. de mer. E. | Dif. de mer. O. | Dist. este desde la línea meridiana. |
|---|---|---|---|
| 2 | 1167.0 | | 1167.0 |
| 3 | 1042.1 | | 2209.1 |
| 4 | | 556.0 | 1653.1 |
| 5 | | 786.9 | 866.2 |
| 6 | | 564.9 | 301.3 |
| 1 | | 301.3 | 000.0 |

Este trabajo se comprueba él mismo porque su resultado final debe ser 0.

esta regla : « En el sistema métrico » la escala para este límite de error es $= \frac{1}{\text{término medio de la longitud de los lados} \times 5)}$.

Pero si se necesita calcular el área del plano corregido con rigurosa exactitud, se puede hacer según el principio siguiente. (Véase fig. 5.)

Supongamos trazada una línea meridiana N-S por el vértice 1 del extremo oeste del polígono y líneas (llamadas *distancias medias*) trazadas (como las indicadas con puntos en la figura) en ángulos rectos á dicho meridiano, desde el centro de cada lado del polígono. Entonces, si cada una de las distancias medias de dichos lados, que tienen diferencia de latitud norte, se multiplica por la dif de lat, N corregida de su lado correspondiente; y si cada una de las distancias medias de dichos lados que tengan diferencias de lat S se multiplica por la dif corregida de lat S de su lado correspondiente; si sumamos separadamente todos los productos provenientes del factor dif de lat norte y todos los productos provenientes de la dif de lat S, y sustraemos la menor de estas sumas de la mayor, el residuo será el área del polígono *. Hemos encontrado ya las difs de lat norte y sur corregidas, así como también las difs de mer este y oeste. Las dist medias se encuentran por medio de las últimas, empleando sus mitades; sumando la mitad de las difs de mer E y sustrayendo la mitad de las difs de mer O. De este modo es evidente que la distancia media 2′ del lado 2 es igual á la mitad de la dif de mer E del lado 2. A ésta agréguese la otra mitad de la dif de mer E del lado 2 y la mitad de la dif de mer E del lado 3, y la suma es claramente igual á la distancia media 3′ del lado 3. A esto agréguese la otra mitad de la dif de mer E, del lado 3 y réstese la mitad de la dif de mer O del lado 4 para obtener la distancia media 4′ del lado 4. De ésta réstese la otra mitad de la dif de mer O del lado 4 y la mitad de la dif de mer O del lado 5 para obtener la distancia media 5′, del lado 5 y así de los demás. Este cálculo debe hacerse así :

---

* *Prueba.* Para ilustrar el principio sobre el cual está basada esta regla, represéntese por *ab*, *bc*, *ca*, fig. 6, los tres lados de un polígono triangular de una mensura y por *df* una meridiana trazada por el vértice del extremo oeste *a*. Trácense líneas *bd* y *cf*, perpendiculares á la línea meridiana desde cada vértice y desde el medio de cada lado trácense líneas *we*, *mn*, *so*, perpendiculares también al meridiano y que

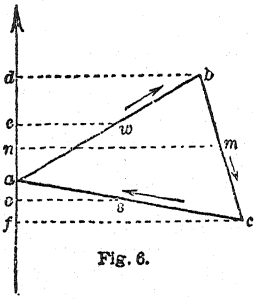

Fig. 6.

representen las dists medias de los lados. Considerando los lados en el orden, *ab*, *bc*, *ca*, es claro que *ad*, representa la dif de lat N del lado *ab*; *fa*, la dif de lat N de *ca*, y *df* la dif de lat S de *bc*. Ahora bien, si multiplicamos la dif de lat N *ad*, del lado *ab* por su dist media *ew*, el producto será el área del triángulo *abd*. De la misma manera la dif de lat N *fa* del lado *ca*, multiplicada por la distancia media *so*, dará el área del triángulo *acf*. Y también la dif de lat S *df* del lado *bc* multiplicada por la distancia media *mn*, dará el área encerrada por la figura entera *dbcfd*. Si de esta área sustraemos las áreas de los dos triángulos *abd*, *acf*, la dif es evidentemente el área del triángulo *abc*, y así con cualquiera otro polígono por complicado que sea.

Mitad de la dif de mer E del lado 2 = $\frac{1,167}{2}$ = 583.5 E = dist media del lado 2.

583.5 E

Mitad de la dif de mer E del lado 3 = $\frac{1,042.1}{2}$ = 1,167.0 E / 521.0 E

1,688.0 E = dist media del lado 3.

521.0 E

Mitad de la dif de mer O del lado 4 = $\frac{556}{2}$ = 2,209.0 E / 278.0 O

1,931.0 E = dist media del lado 4.

278.0 O

Mitad de la dif de mer O del lado 5 = $\frac{786.9}{2}$ = 1,653.0 E / 393.5 O

1,259.5 E = dist media del lado 5.

393.5 O

Mitad de la dif de mer O del lado 6 = $\frac{564.9}{2}$ = 866.0 E / 282.4 O

583.6 E = dist media del lado 6.

282.4 O

Mitad de la dif de mer O del lado 1 = $\frac{301.3}{2}$ = 301.2 E / 150.6 O

150.6 E = dist media del lado 1.

El trabajo se comprueba siempre por sí mismo cuando los dos últimos resultados son iguales.

Hágase luego una tabla en cuyas cuatro primeras columnas se colocan los números, las distancias medias y las difs de lat N y S. Multiplíquese cada distancia media por su correspondiente dif de lat N ó S y colóquese el producto en su propia columna. Súmese cada columna y réstese la suma menor de la mayor.

| Lado. | Dist. media. | Dif. de lat. N. | Dif. de lat. S. | Producto proveniente del factor dif. de lat. N. | Producto proveniente del factor dif. de lat. S. |
|---|---|---|---|---|---|
| 1 | 150.6 | 1013.8 | | 152678 | |
| 2 | 583.5 | 298.4 | | 174116 | |
| 3 | 1688 | | 392 | | 661696 |
| 4 | 1931 | | 642.3 | | 1240281 |
| 5 | 1259.5 | 142.6 | | 179605 | |
| 6 | 583.6 | | 420.4 | | 245345 |
| | | | | 506399 | 2147322 |
| | | | | | 506399 |
| | | | | 43560)1640923)37.67 Acres. | |

El residuo será el área de la mensura en pies cuadrados, la cual dividida por 43,560 (número de pies cuadrados que tiene un acre) será el área en acres. En este ejemplo tenemos 37.67 acres. (*N. del T.* — Todo esto se aplica á cualquiera unidad de medida, pies, metros, etc. Si se toman las medidas en metros, el residuo será metros cuad.)

Sólo falta ahora calcular los rumbos corregidos y las longitudes de los lados, las cuales están necesariamente cambiadas por la adopción de las diferencias corregidas de latitud y de meridianos. Para encontrar la dirección de cualquier lado, divídase su dif de mer (E ú O) por su lat (N ó S), búsquese el cociente en la tabla de tangentes naturales; y el ángulo opuesto á él será el ángulo de la dirección ó rumbo que se desea. De este modo tenemos por dirección del lado 1 $\frac{301.3\ O}{1,013.8\ N}$ = =.2972=tangente natural, opuesta en la tabla al ángulo que se busca de 16°33'. La dirección por tanto es N 16°33' O.

Para tener la magnitud de cualquier lado : en la tabla de cosenos naturales, tómese el coseno opuesto al ángulo de la dirección corregido y divídase la lat corregida (N ó S) del lado por el coseno. Así, para tener la magnitud del lado 1 encontramos opuesto á 16°33′ el coseno .9586 y

Lat. Cos.
1,013.8 ÷ .9586 = 1,057.6 distancia requerida.

La tabla siguiente contiene todas la correcciones de la medida anterior; por

| Lado. | Dirección ó rumbos. | Distancia. |
|---|---|---|
| 1 | N 16° 33′ O | 1057.6 |
| 2 | N 75° 39′ E | 1204.0 |
| 3 | S 69° 23′ E | 1113.3 |
| 4 | S 40° 53′ O | 849.6 |
| 5 | N 79° 44′ O | 800.1 |
| 6 | S 53° 21′ O | 704.3 |

consiguiente, si las direcciones y distancias están correctamente trazadas, cerrarán perfectamente. Se aconseja al ayudante que practique haciendo esto; y también dividiendo el trazado en triángulos y calculando el área; de este modo comprenderá pronto el gran cuidado que se requiere para obtener resultados exactos.

Las apuntaciones siguientes pueden ser útiles á menudo : 1.° Evítese tomar rumbos y distancias á lo largo de una línea limítrofe tortuosa como *abc*, fig. 7;

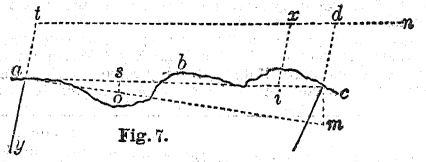

Fig. 7.

evántese ésta por medio de perpendiculares á una línea recta *ac* que se trazará en lugar de aquélla. 2.° Cuando se desee medir una línea recta desde *a* hasta *c* y no se pueda dirigir el instrumento precisamente hacia *c*, debido á la interposición de árboles ú otros obstáculos, tírese primero una línea de ensayo *am* tan próxima y en la misma dirección de la línea *ac* como se pueda; mídase *mc* y hágase la siguiente proporción ; *am* : *mc* : : 100 : *x*. Trácese *ao* = 100 pies ó metros y *os* igual á *x* y córrase la línea final *asc*. Si *mc* es muy pequeña, calcúlense perpendiculares *os* para cada 100 pies ó de 30 en 30 metros á lo largo de *am*, evitando así la necesidad de seguir una segunda línea. 3.° Cuando *c* es visible desde *a*, pero el terreno inter-

Fig. 8.

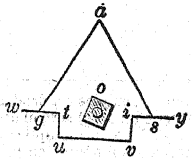

Fig. 9.

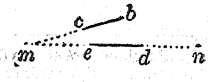

Fig. 10.

puesto hace dificultosa su medida directamente por los pantanos, etc., prolónguese el lado *y a* hasta el terreno bueno en *t*, y luego haciendo el ángulo *ytd* igual á *yac*, trácese la línea *tn* hasta un punto *d* en el cual el ángulo *ndc* se encuentre por tanteo igual al ángulo *atd*. Rara vez es necesario hacer más de un tanteo para encontrar este punto *d*; porque suponiendo hecho un ensayo en *x* y no en *d*, véase dónde encuentra á la línea *ac* en *i*, mídase entonces *ic*, y sígase desde *x*, haciendo la línea *xd* = *ic*. 4.° Caso de que nos encontremos con un pedazo de terreno ó lago fig. 8, muy irregulares, rodéese por líneas rectas, mídanse éstas, y levántese el

borde por perpendiculares á aquellas líneas. 5.° Si al trazar una línea recta de *w* hacia *y*, fig. 9, encontramos un obstáculo *o*, trácese un ángulo recto *wtu*, mídase cualquiera distancia *tu*, hágase *tuv* = 90°; mídase *uv*; hágase *uvi* = 90°; hágase *vi* = *tu* y hágase *viy* = 90°. Entonces *ti* será igual á *uv* y la línea *iy* será prolongación de *wt*. Con menos trabajo, en *g* hágase *tga* = 60°; mídase cualquier distancia *ga;* hágase *gas* = 60° y *as* = *ga;* hágase *a s i* = 60°. Entonces *gs* es = *ga*, ó *as* y la línea *is* prolongada hacia *y* estará en línea recta con *wt*. 6.° Estando situado entre dos objetos *m* y *n* y deseando colocarme en la línea recta que los une, acuesto un bastón *cb* en el terreno y lo pongo en la dirección de uno de los objetos *m;* luego yendo hacia el extremo *c*, encuentro que no se halla en la dirección del otro objeto. Por medio de tanteos sucesivos se encuentra la posición *ed* que señala á ambos objetos y en consecuencia se hallará en su mismo alineamiento.

## CADENAS Y CINTAS

**Cadena.** Los ingenieros (americanos) han abandonado la cadena de Gunter de 66 pies (20.11 mets) dividida en 100 eslabones de 7.92 pulgs (.2011 mets) cada uno y úsanlas de 100 pies (30.479 mets) con 100 eslabones de 1 pie (.3047 mets) cada uno, y calculan las áreas en pies cuad, cuyo número dividido por 43560 los convierte en acre y sus decimales. El Gobierno de los E. U. emplea la cadena de Gunter en las mensuras.

Las cadenas se construyen de alambre de hierro ó acero. Cada eslabón está doblado en sus extremidades formando un anillo de conexión con el adyacente, ya directamente como en la cadena patentada de Grumman, ó más comúnmente por pequeños eslabones. El desgaste de estos anillos es causa de errores, pues aumentan el largo de la cadena. De aquí la necesidad de compararla de vez en cuando con una medida fija normal.

**Cintas.** Debido á las actuales facilidades en la fabricación de cintas de acero, se está abandonando el uso de la cadena. Siendo la cinta más liviana requiere menos tensión, y no teniendo eslabones que se desgasten, su tamaño es más constante. Hasta cierto punto reemplaza la percha para la mensura de las bases en los trabajos geodésicos. Las cintas de acero se hacen en piezas enterizas hasta de 500, 600 y aun de 1,000 pies (152.40; 182.88; 304.79 metros); pero las de 100 pies (30.48 mets) son las más usadas. Las cintas muy largas se quiebran más fácilmente con el uso. Estas roturas son difíciles de soldar, mientras que la torcedura de un eslabón apenas altera temporalmente la longitud de una cadena. El paso de un carro puede hasta quebrar una cinta de acero. Sin embargo, la ligereza, limpieza y seguridad de la cinta de acero compensan aquellas desventajas; las cuales, además, pronto aprende á evitarlas el agrimensor.

Las cintas empleadas en las mensuras de campos son, por lo general, angostas (3 á 6 mm) y su espesor de .3 á .6 mm, y están graduadas por medio de pequeños remaches de cobre, separados, generalmente, por espacios de 5 pies y de 1 pie en los 10 pies de cada extremo. *

Las que se emplean en la ciudad son más anchas, de .25 á .5 pulgs (6 á 12 mm) y de menos grueso, de .007 á .010 pulgs (.17 á .25 mm), divididas generalmente en décimos de pie.

**Agujas.** Son generalmente de alambre, agudas en un extremo, y el otro en forma de anillo; se clavan con facilidad en terrenos no muy pedregosos. Cada aguja lleva un pedazo de franela roja en el anillo para hacerla visible entre la yerba.

**Correcciones de la cinta por seno y alargamiento.** (*Obs. del T.* — Hemos construído este diagrama, reemplazando el que trae el autor en medidas inglesas, transformando de igual manera los ejemplos anexos.) †

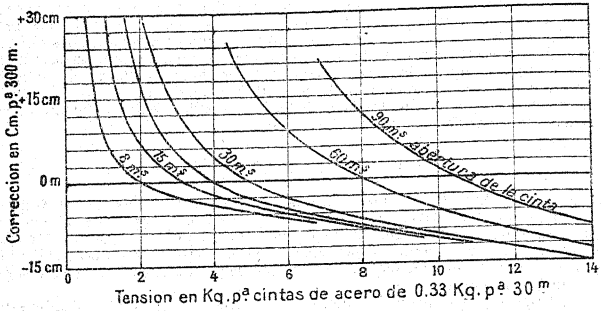
---

* El tamaño de la cinta varía mucho con los diversos fabricantes, y por tanto para aplicarles las correciones se debe conocer muy bien el espesor y su peso por unidad de longitud.

† Deducido de los diagramas construídos por Mr. J. O. Clark de los trabajos del Club de Ingenieros de Filadelfia, abril 1901, vol. XVIII, n.° 2, y de la fórmula : Alargamiento en pies $= \frac{PS}{EA}$ en que

P = tensión en lbs.
S = longitud empleada de la cinta en pies.
E = módulo de elasticidad del acero = 27,500,000 lbs por pulg cuad.
A = área de la sección transversal de la cinta con peso de .75 lbs por 100 pies = .0022 pulgs cuads; y de la ecuación de la parábola se deduce que el acortamiento

**Diagrama en Sistema Métrico.** Este diagrama demuestra que una abertura de 60 m de cinta, con el peso de .33 kg por 30 m, se requiere una tensión de 8 kg para reducir á 0 (cero) la corrección; otra abertura de 30 m, 4.8 kg; para



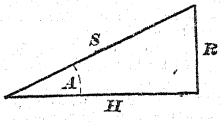
8 m, 2 kg, etc. Con estas tensiones (que se llaman normales), los efectos opuestos, por el seno que hace la cinta y la tensión, se compensan. Con mayores tensiones el alargamiento supera á la reducción producida por el seno, y viceversa.

**Las cintas de otros pesos** necesitan tensiones proporcionales á sus pesos. Así en una cinta de cualquier tamaño que pese 1 kg para 30 m (llamando $y$ la tensión para una corrección dada en una cinta normal que pese .33 kg para 30 m) tendremos $x : y = 1 : .33 = 100 : 33$; de donde $x = \frac{100}{3}\, y = 3\, y$.

Ahora, al contrario, *búsquese la corrección*, dada una tensión de 4 kg para una cinta de 15 m que pese .22 kg por 30 m.

Para producir el mismo error en la cinta que pesa .33 por 30 m se necesita una tensión $y = 4 \frac{.33}{.22} = 6$ kg. Buscando en el diagrama de la columna de 6 kg y en la curva de 15 m, se encuentra la corrección $= -6$ cm.

**Correcciones debidas á la temperatura.** Las cintas se gradúan generalmente calculando su longitud normal á 62° F=16°7 C. Para cintas corrientes de acero, la corrección por temperatura es como de .0000037 m por metro y por grado C.



Las correcciones de temperaturas no son exactas puesto que la temperatura de la cinta no se puede determinar con exactitud. Las mensuras que requieren gran exactitud deben hacerse, por consiguiente, con tiempo nublado ó de noche, manteniendo la cinta y el termómetro separados del suelo.

Cuando se hacen mensuras en **terrenos inclinados**, la cadena ó la cinta

---

debido al seno que forma la cinta es en pies $= \frac{W^2 S^3}{24 P^2}$ en que W es el peso de la cinta en lbs por pie. Excepto para tensiones muy suaves, esta última fórmula da prácticamente los mismos resultados que la ecuación de la catenaria, la que es exacta pero mucho más complicada.

*N. del T.* — La primera fórmula en el sistema métrico es la siguiente: Alargamiento en metros $= \frac{P \times S}{E \times A}$; donde P se da en kilogramos; S en metros; E = 1,925,000 kg por cm cuadrado = módulo de elasticidad del acero (equivalente al del autor); A = área de la sección transversal de la cinta = 0.01419 cm cuad. Pesa. 337 kg por 30 metros.

deben mantenerse lo más horizontalmente posible, proyectando en el terreno por medio de una plomada el extremo en alto de la cinta. O bien, se mide con la cinta paralela al terreno inclinado y se corrige la medida con las siguientes fórmulas :

$$\frac{H}{S} = \cos A; \quad H = S \cos A; \quad S = \frac{H}{\cos A} = H \sec A;$$

$$\frac{R}{H} = \text{tang } A; \quad R = H \text{ tang } A;$$

$$\frac{R}{S} = \text{sen } A; \quad R = S \text{ sen } A.$$

## TRAZADO DE LA MERIDIANA

### Por medio de una estrella circumpolar.

(1) Vista desde un punto O de la tierra (figs. 1 y 2), una estrella circumpolar *e* (estrella próxima al polo P) parece describir, diariamente * y en sentido opuesto al movimiento de las manillas de un reloj, una pequeña circunf *euwl*, alrededor del polo. El ángulo POe, POu, etc., subtendido por el radio Pe, Pu, etc., de este círculo, ó sea la distancia aparente de la estrella al polo, se llama **distancia polar.** Las distancias polares de las estrellas varían muy poco de año en año (véase tabla 3). Varían menos **durante** el año. En el caso de la estrella Polar, esta última variación llega á unos 50 segundos de arco.

(2) El ángulo NOP, que mide la **altura** del polo sobre el horizonte NESW, es= á la **latitud** del punto O de observación. La **declinación** es igual á su distancia angular norte ó sur del ecuador celeste. Por eso la declinación del polo es=90° y la de cualquier estrella es=á 90° — su distancia polar.

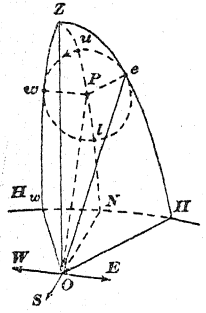


Fig. 1.

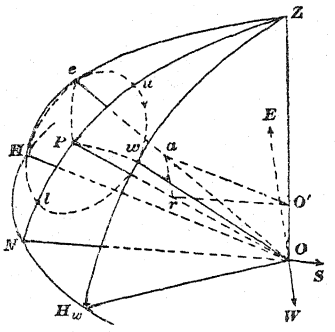

Fig. 2.

(3) Sea ZeH un arco de círculo vertical † que pasa por una estrella circumpolar *e* y sea H el punto en que este arco encuentra al horizonte NESW. El ángulo NZH cuyo vértice está en el zénit Z, ó el NOH en el punto de observación O, formado por el meridiano NZO y el plano HZO del círculo vertical de la estrella ó sea el arco NH se llama el **acimut** ‡ de la estrella. Si este ángulo NOH se traza desde OH en el terreno, la línea ON estará en el plano del **meridiano** NZS y será la **línea norte-sur** ‖.

(4) Cuando una estrella se encuentra en el meridiano ZN del observador, arriba ó debajo del polo P como en *u* ó *l*, se dice que está, respectivamente, en su **paso superior ó culminación** ó en su **paso inferior.** Su acimut es entonces **=cero**; la línea HO coincide con el meridiano ON.

(5) Cuando la estrella llega á su mayor distancia al Este ó al Oeste del polo, como en *e* ó *w*, se dice que está **en su máxima elongación Este ú Oeste** §.

---

* En 23 h. 56.1 m.

† Un círculo máximo es la sección en la esfera hecha por un plano que pasa por su centro. Un círculo vertical es un círculo máximo que pasa por el zénit Z.

‡ Los astrónomos toman generalmente el acimut, contando desde el extremo sur hacia los puntos oeste, norte y este y luego al sur; pero para nuestro objeto es mucho más conveniente medirlo desde el norte, hacia el este ó el oeste, según sea el caso.

‖ El punto N en el horizonte, se llama el *Norte* y no se debe confundir con el *polo* norte P.

§ Vista desde el ecuador una estrella, en cualquiera de estas dos posiciones, está como el mismo polo, en el horizonte; y las dos líneas Pe, Pw la unen con el polo y forman una perpendicular al meridiano. El acimut de la estrella será entonces igual á su distancia polar. Pero en otras latitudes Pe y Pw forman ángulos agudos con el meridiano, como se puede ver, y estos ángulos decrecen, y el acimut de la estrella aumenta más con su elongación á medida que aumenta la latitud.

**(6) El ángulo horal** de una estrella cualquiera, en un momento dado, es el tiempo transcurrido desde que alcanzó su culminación *.

**(7)** Es evidente que el acimut de una estrella cambia constantemente. En las estrellas circumpolares varía de 0° al máximo de su elongación y retrocede á 0° dos veces diariamente, pues la estrella parece girar alrededor del polo; pero cuando la estrella se encuentra cerca de cualquiera de sus elongaciones, el cambio de acimut se efectúa tan lentamente que, por algunos minutos, es apenas perceptible y parece que la estrella se mueve verticalmente.

**(8)** Tenemos para cualquiera estrella cuya declinación (=90° — su distancia polar) exceda la latitud del punto de observación †:

$$\left.\begin{array}{l}\text{seno del acimut de la estrella}\\ \text{en su elongación}\end{array}\right\} = \frac{\text{seno de la distancia polar de la estrella}}{\text{cos de latitud del punto de observación}}$$

ó véase **(11)** y tabla 3. Cuando la latitud > que la declinación, el seno acimut > 1, y en este caso no se aplica esta fórmula.

**(9)** Las siguientes estrellas circumpolares son útiles para determinar el meridiano. (Véase fig. 3.)

| Constelaciones. | Letras. | Nombres. |
|---|---|---|
| Osa menor | $\alpha$ (alfa) | Polar |
| — mayor | $\varepsilon$ (epsilon) | Aliot |
| — — | $\zeta$ (zeta) | Mizar |
| Casiopea | $\delta$ (delta) | Delta ‡ |

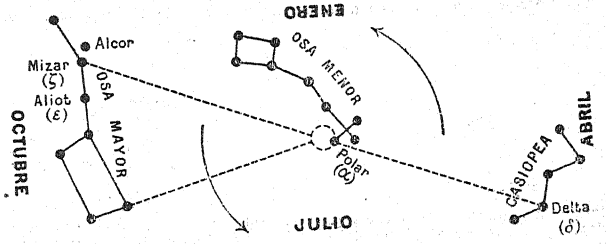

**Fig. 3.**

**(10)** La Polar se encuentra muy bien situada para la determinación del meridiano, pues su distancia polar es más ó menos de 1 $^1/_4$ grado. En la fig. 3 se ven las estrellas circumpolares, en la posición que ocupan á media noche en julio; invertidas quedan como se ven en enero, con el lado izquierdo hacia arriba como se ven en abril y para octubre con el lado derecho hacia arriba ‖.

**(11)** La tabla 3 da las distancias polares de la Polar y los logaritmos de sus

---

* En la latitud 40° N el ángulo horal ZP$e$ = ZP$w$ de la polar en su elongación, ó sea igual á 5 h 55 m del tiempo solar. *Advertencia.* Nótese que, sólo para el observador situado en el ecuador, la elongación *no* ocurre á los 90° del meridiano.

† En el triángulo esférico ZP$e$, tenemos

$$\frac{\text{seno } e\text{ZP}}{\text{seno ZeP}} = \frac{\text{seno Pe}}{\text{seno PZ}}$$

pero como ZeP = 90°, sen ZeP = 1. También sen PZ = cos(90° — PZ) y $e$ZP = al acimut $e$ De donde seno acimut de $e$ = $\frac{\text{sen Pe}}{\text{sen PZ}} = \frac{\text{sen dista polar PO}e}{\text{cos latitud}}$.

‡ La δ de Casiopea la llamamos Delta por brevedad.

‖ *La Polar* se encuentra fácilmente por medio de dos conocidas estrellas llamadas *punteras*, en el trapecio de la Osa mayor, fig. 3, que forman la parte posterior de esta constelación. La línea que une estas dos estrellas prolongada pasa cerca de la Polar. La Osa mayor tiene una cola formada por tres estrellas y, de modo análogo, la Osa menor tiene otra cerca de cuyo extremo están la Polar y sus vecinas. La Polar está á mitad de línea que une á Delta y Mizar. La Polar se encuentra al extremo del brazo derecho de una cruz que forma ella con tres de menor brillo. En la fig. 3 esta cruz está invertidv

senos para el 1.° de enero, cada 3 años, de 1900 á 1930 inclusive, el log de los cosenos de cada cinco grados de latitud, de 20° á 50°, y los correspondientes acimutes de la Polar en su máxima elongación. Los valores intermedios se encuentran por interpolación.

(12) **Por la observación de la Polar en su máxima elongación.** Este método tiene la ventaja de que durante y cerca de su máxima elongación, aquella estrella parece que se mueve sobre una vertical, durante algunos minutos, y su acimut durante este tiempo no cambia apreciablemente; pero en algunas épocas (véase tabla 1) dicha elongación se efectúa de día, y este método no se puede emplear entonces. Véase (18), (19) y (22). Tampoco se puede emplear en ningún tiempo, en lugares situados al sur ó á menos de 4° lat N, porque en éstos no es visible la Polar.

(13) La tabla 1 da las horas aproximadas de la máxima elongación de la Polar en ciertos días de 1900 é instrucciones para calcular las horas en otros días. O bien obsérvese la Polar en conexión con cualquiera de aquellas estrellas que se encuentran aproximadamente en línea con ella y el Polo, como Delta, Mizar y Aliot (véase fig. 3). La hora de la elongación es bastante aproximada para determinar el acimut, por la cesación del movimiento horizontal durante la observación.

(14) Quince ó veinte minutos antes de la hora de la elongación colóquese el tránsito (véase 21) bien centrado sobre un punto marcado en una estaca, clavada previamente en el suelo.

(15) El instrumento debe tener lo necesario para iluminar los pelos del retículo. Esto se puede lograr por medio de una linterna sorda colocada de modo que no arroje luz sobre los ojos del observador, ó mejor aún, con un pedazo de hojalata, cortada y perforada como en la fig. 4, doblado en ángulo de 45° como en la fig. 5

Fig. 4.

Fig. 5.

y pintado de blanco en la superficie que ve al anteojo. El anillo que se forme con la tira larga se coloca alrededor del objetivo. Una luz, cubierta para el observador, se sitúa á un lado del instrumento, de modo que sus rayos caigan sobre la superficie inclinada y blanqueada de la hojalata y entren reflejados al anteojo.

(16) Hágase que el pelo vertical corte la Polar y por medio del tornillo tangente sígase á la estrella en su aparente curso hacia *la derecha*, si se acerca á la elongación *oriental* y *viceversa*, manteniendo el pelo sobre la estrella todo lo posible. A medida que se acerca á su máxima elongación, la estrella, parece moverse con mayor lentitud. Cuando parece que se mueve verticalmente á lo largo del pelo es porque ha llegado, prácticamente, á su máxima elongación, y el plano vertical del tránsito, *con el pelo cortando la estrella*, se encontrará en el mismo plano vertical de la estrella. Bájese el anteojo y fíjese un punto en la dirección de la vertical á unos cien metros ó más del tránsito*. Hágase girar éste inmediatamente (en sentido horizontal, 180°), vuélvase á ver la estrella, vuélvase á bajar el anteojo, y, si la visual coincide exactamente con la primera marca hecha, ambas se encontrarán en el plano vertical de la estrella. De no ser así, márquese la dirección de la visual y fíjese una tercera marca entre las dos anteriores. La visual dirigida á esta tercera marca se encontrará en el plano requerido, desde el cual debe trazarse el acimut, como en el (8), hacia el meridiano, ya sea á la izquierda de la elongación oriental ó á la derecha de la occidental.

(17) Para distinguir la estaca á mayor distancia y para señalarla de noche, se puede hacer uso de una placa ó mira.

(18) **Por observación de la estrella Polar en su culminación.** Debido

* La estaca debe estar iluminada, lo que se consigue alumbrando la cara de la estaca que ve al instrumento, ó mejor, colocando una hoja de papel detrás de la estaca y una luz detrás de la hoja; de este modo, el pelo del anteojo y la punta del lápiz con que el ayudante marca sobre la estaca la proyección del pelo, se destacan como sombras en el papel.

á sus dificultades este método se emplea sólo cuando no es posible hacer uso del método de elongación. Consiste aquél en observar la Polar en conexión con otras estrellas circumpolares (como Mizar * ó Delta) hasta que la Polar se vea en el mismo plano vertical con la otra, y luego esperando un corto espacio de tiempo conocido T, como se dice después, † hasta que la Polar llegue á su culminación en donde se observa ésta. La visual está entonces en el meridiano. En sus culminaciones Mizar y Delta están demasiado cerca del zenit, para ser observadas con exactitud en las latitudes nortes de 25° y 30° respectivamente. En sus pasos inferiores se encuentran demasiado cercanas al horizonte para servirse de ellas en lugares mucho más bajos de 38° de latitud norte. Generalmente, Delta se observa bien en su paso inferior de febrero á agosto y Mizar durante el resto de año.

| | Mizar T= | Delta T= |
|---|---|---|
| En 1900 | 2.6 min | 3.4 min |
| En 1910 | 6.5 — | 7.2 — |
| Aumento medio anual, 1900-1910 | .39 min | .38 min |

(19) **Por la observación de la Polar en cualquier punto de su curso.** La tabla 1 da la hora media solar de la culminación superior de la Polar para el 1.° de cada mes en 1900, é instrucciones para conocer las horas en las otras fechas; y la tabla 2 da el acimut de la Polar correspondiente á los diversos valores de su ángulo horal en la hora media solar común para diversas latitudes, desde 30° á 50° para los años 1901 y 1906. Para los ángulos horales y latitudes intermedias de los contenidos en las tablas, se pueden obtener los acimutes por interpolación. Véase la advertencia y fórmula pág. 300.

(20) La hora *local*,‡ de la observación debe conocerse con exactitud y se deducirá de ella la hora de la anterior culminación (como se obtiene en la tabla 1). La diferencia es el ángulo horal. Si éste, así encontrado, es de 11 h 58 min ó menos, la estrella se encuentra al oeste del meridiano. Si es mayor de 11 h 58 min, la estrella se encuentra al este del meridiano. En este caso réstese el ángulo horal de 23 h 56 min y éntrese en la tabla con el residuo como ángulo horal. Véase fig. 1.

(21) Cuando no se requiere gran exactitud, puede observarse la Polar á la simple vista por medio de una plomada. Un ladrillo ú otro objeto pesado puede servir para hacer una plomada. Ésta debe colgar sobre un balde de agua y se puede usar una pínula de brújula ó cualquier aparato con una ranura exactamente recta, como de 1½ mm de ancho. La pínula debe mantenerse exactamente vertical, pero debe poderse ver por ella horizontalmente á algunos metros al este y al oeste. La plomada y la pínula deben estar separadas unos 4 ó 5 metros por lo menos y colocadas de manera que por la pínula se vean la estrella y la plomada. La cuerda de la plomada debe estar iluminada. Sería conveniente hacer estos preparativos la noche antes de la observación. Cuando la estrella alcanza su máxima elongación, la vista debe colocarse en la misma línea que la plomada y la estrella. Desde la línea, así obtenida, trácese el acimut, hacia el oeste para la elongación oriental y viceversa.

(22) **Por estrellas á igual altura.** Este método, aplicable tanto en las latitudes sur como á las septentrionales, consiste en observar una estrella cuando se encuentra á alturas iguales sobre el horizonte al este ú oeste del meridiano, fijando así en el horizonte dos puntos de igual y opuesto acimut. El meridiano pasará por todo el medio entre los dos puntos.

(23) **Por sombras solares simétricas (aproximado),** fig. 6. Durante los solsticios (hacia junio 21 y diciembre 21), el rastro *abcd* recorrido antes y después de mediodía por el extremo de la sombra solar *Oa*, etc., de un objeto vertical O, ó por la sombra de un nudo hecho en la cuerda de una plomada suspendida en O, cortará un arco de círculo *aNd*, descripto alrededor de O á iguales distancias *am*, *md*, del meridiano ON. Las observaciones deben hacerse durante dos horas antes y después del mediodía. En el equinoccio de estío (marzo 21) la línea así determinada se encontrará algo al oeste, y en el equinoccio de otoño (sep-

---

* Mizar se reconoce por la pequeña estrella Alcor, situada cerca de ella.

† Deducido de los valores calculados en tiempo astronómico (pág. 269) por las Mensuras geodésicas y de las costas de los EE.

‡ La hora local corresponde con la hora normal (pág. 270) tan sólo en los meridianos normales. Para otros puntos agréguese á la hora normal 4 minutos por cada grado de longitud al este de un meridiano normal y *viceversa*.

tiembre 21) algo al este, del meridiano exacto y á menos de 2½ minutos de arco. Para fechas intermedias el error es casi proporcional al período de tiempo trans-

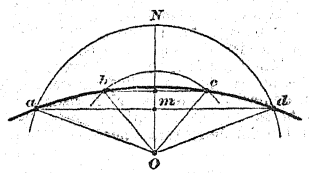

**Fig. 6.**

currido desde las citadas fechas. Es conveniente trazar varios arcos de diversos radios O*a*, O*b*, etc., marcando los dos puntos en que el paso de la sombra intersecte cada arco, y tomando el promedio de todos los resultados. Se puede emplear en vez del extremo de la sombra un pequeño pedazo de hoja de lata agujerado en el centro, colocándolo verticalmente sobre O; el punto brillante formado por la luz que pasa por el agujero sustituye á la sombra dicha.

## Tabla 1.

**Hora común aproximada de la elongación y culminación de la estrella Polar** en lat 40º N, long 90º O de Greenwich para el 1.º de cada mes en 1900. La hora de esta tabla es la solar media. **Las horas P. M.** (entre mediodía y media noche) aparecen en tipo negro.

En la latitud 25º la elongación oeste ocurre más tarde y la este más temprano ..... } cerca
En la latitud 50º las elongaciones oeste ocurren más temprano y las del este más tarde ..... } de 2 minutos.

La corrección de longitudes es de poco menos de un minuto de tiempo en cualquier parte de los E.U.

Para otros días del mes dedúzcase 3.94 min por cada día subsiguiente.

Por lo común las horas van retardando un poco cada año. En 1904 estarán unos 5½ minutos en retardo; pero en 1905 estarán sólo 3 minutos más en retardo que en 1900. Esta discrepancia se debe á que el año 1904 es bisiesto.

Como esta tabla sirve principalmente para alertar al observador y como éste debe estar en su puesto 15 ó 30 minutos antes de aquellas horas, el aumento gradual de las horas es de poca consecuencia. La posición de la estrella en su elongación máxima se determina por observación.

Al observar la estrella Polar en su culminación, cuando el cambio de acimut es más rápido, un error de dos minutos en tiempo se traduce por un error como de un minuto en el acimut.

| En su elongación un error de tiempo de | produce un error en el acimut menor de |
|---|---|
| 20 minutos | 30 segundos |
| 10 — | — de 6 — |
| 5 — | — de 2 — |
| 1 minuto | como .06 segundo. |

En todas las latitudes hay 11 h 58 m (tiempo solar medio) entre dos pasos sucesivos de una estrella por el meridiano. El tiempo entre las elongaciones sucesivas varía con las latitudes.

| 11 29 | 11 28 | 0 11 | 0 11 | 0 12 | 0 13 | 0 14 |
| 11 33 | 11 32 | 0 9 | 0 9 | 0 10 | 0 11 | 0 12 |
| 11 37 | 11 37 | 0 8 | 0 8 | 0 8 | 0 9 | 0 10 |
| 11 41 | 11 41 | 0 6 | 0 6 | 0 7 | 0 7 | 0 8 |
| 11 45 | 11 45 | 0 5 | 0 5 | 0 5 | 0 6 | 0 6 |
| 11 50 | 11 49 | 0 3 | 0 3 | 0 3 | 0 4 | 0 4 |
| 11 54 | 11 54 | 0 1 | 0 1 | 0 2 | 0 2 | 0 2 |

Cuando la estrella está cerca de su máx elong (áng horales entre 5 y 7 horas) á pequeñas variaciones del acimut corresponden grandes variaciones en el ángulo horal.

## Tabla 3.

### ESTRELLA POLAR. DISTANCIAS POLARES Y ACIMUTES EN LAS ELONGACIONES

| Año. | Dist polar de la Polar. | Log del seno dist pol. | Acimutes en las elongaciones en las latitudes de: 20° | 25° | 30° | 35° | 40° | 45° | 50° |
|---|---|---|---|---|---|---|---|---|---|
| | ° ′ ″ | | ° ′ | ° ′ | ° ′ | ° ′ | ° ′ | ° ′ | ° |
| 1900 | 1 13 33 | 8.33 027 | 1 18.3 | 1 21.1 | 1 24.9 | 1 29.8 | 1 36.1 | 1 44.1 | 1 54.4 |
| 1903 | 1 12 37 | 8.32 472 | 1 17.3 | 1 20.1 | 1 23.8 | 1 28.7 | 1 34.8 | 1 42.7 | 1 53.0 |
| 1906 | 1 11 41 | 8.31 910 | 1 16.3 | 1 19.1 | 1 22.8 | 1 27.6 | 1 33.6 | 1 41.4 | 1 51.5 |
| 1909 | 1 10 45 | 8.31 341 | 1 15.3 | 1 18.1 | 1 21.7 | 1 26.4 | 1 32.3 | 1 40.1 | 1 50.1 |
| 1912 | 1 9 49 | 8.30 765 | 1 14.3 | 1 17.0 | 1 20.6 | 1 25.2 | 1 31.1 | 1 38.7 | 1 48.6 |
| 1915 | 1 8 53 | 8.30 181 | 1 13.3 | 1 16.0 | 1 19.5 | 1 24.1 | 1 29.9 | 1 37.5 | 1 47.2 |
| 1918 | 1 7 58 | 8.29 594 | 1 12.3 | 1 15.0 | 1 18.5 | 1 23.0 | 1 28.7 | 1 36.4 | 1 45.7 |
| 1921 | 1 7 2 | 8.28 999 | 1 11.4 | 1 14.0 | 1 17.4 | 1 21.9 | 1 27.5 | 1 34.8 | 1 44.3 |
| 1924 | 1 6 7 | 8.28 401 | 1 10.4 | 1 13.0 | 1 16.3 | 1 20.7 | 1 26.3 | 1 33.5 | 1 42.9 |
| 1927 | 1 5 12 | 8.27 794 | 1 9.4 | 1 11.9 | 1 15.3 | 1 19.6 | 1 25.1 | 1 32.2 | 1 41.4 |
| 1930 | 1 4 16 | 8.27 169 | 1 8.4 | 1 10.9 | 1 14.2 | 1 18.5 | 1 23.9 | 1 30.9 | 1 40.7 |
| Log cos lat | | | 9.97 299 | 9.95 728 | 9.93 753 | 9.91 337 | 9.88 425 | 9.84 949 | 9.80 800 |

Debido á los cambios de la Polar durante el año, las posiciones dadas en la tabla pueden á veces variar hasta en un minuto. El error es mayor en las altas latitudes.

Teniendo la dist polar norte, $p$, de una estrella, y la latitud, L, del punto de observación, la declinación de la estrella será $=d=90-p$; y el **acimut** $a$ de la estrella, correspondiente á cualquier ángulo horal, $h$, se **puede** encontrar por las fórmulas siguientes:

$$\text{Tang M} = \frac{\cot p}{\cos h} = \frac{\text{tang } d}{\cos h}. \quad \text{Entonces} \quad \text{Tang } a = \frac{\cos \text{M tang } h}{\cos (\text{M} - \text{L})}.$$

Las declins, $d$, de la Polar se publican en las efemérides. En éstas se encuentran las dist polares con más exactitud que en la tabla 3.

**Advertencia.** Cuando se quiere determinar la meridiana con la aproximación de un minuto de arco, deben emplearse varios métodos de observación y comparar sus resultados. Por ej.: obsérvese la Polar tanto al Este como al Oeste y otra estrella al sur del zénit y á iguales alturas.

*Nota.* Si la Polar se observa en uno de los crepúsculos, se puede trabajar sin necesidad de iluminar artificialmente los pelos del anteojo. Para las horas de máx elongs véase la tabla 1.

### Conversión de los arcos en tiempo, y viceversa.

| Arco. Tiempo. | Tiempo. Arco. |
|---|---|
| 1° = 4 minutos. | 24 horas = 360° |
| 1′ = 4 segundos. | 1 hora = 15° |
| 1″ = .0666 segundo. | 1 minuto = 0°15′ |
| | 1 segundo = 0°0′15″ |

# TRÁNSITO DE INGENIERO

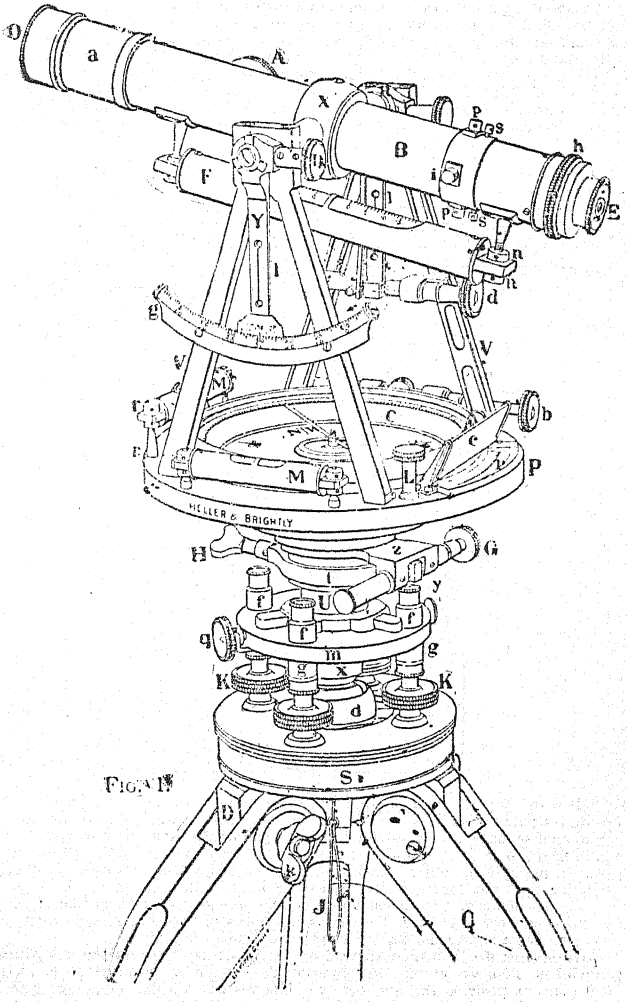

FIGURA 19

Los detalles del tránsito lo mismo que los del nivel, varían según los diferentes fabricantes y el uso á que se destinan. Lo describiremos en su forma moderna como los hacen Heller y Brightly, de Filadelfia. Sin el **nivel largo de burbuja** F, fig. 1, que está debajo del anteojo, y sin el **arco graduado** *g*, la figura representa un **tránsito común**; pero con estos accesorios, ó más bien con un **círculo** graduado en lugar del **arco**, se tiene un **teodolito completo**.

BDD, **fig. 2**, es **la cabeza de la trípode**. Las roscas del tornillo en *v* reciben el tornillo de una tapa de madera que sirve de protección á la cabeza de la trípode cuando ésta no está en uso. SSA es la **placa paralela inferior**. Después de haberse puesto el tránsito muy próximamente en el centro de una estaca, la placa movible *ddcc* nos permite, aflojando ligeramente los **tornillos, de nivelar** K, mover un poco la parte superior del instrumento horizontalmente, y de este modo colocar la plomada exactamente sobre el centro de la estaca con más

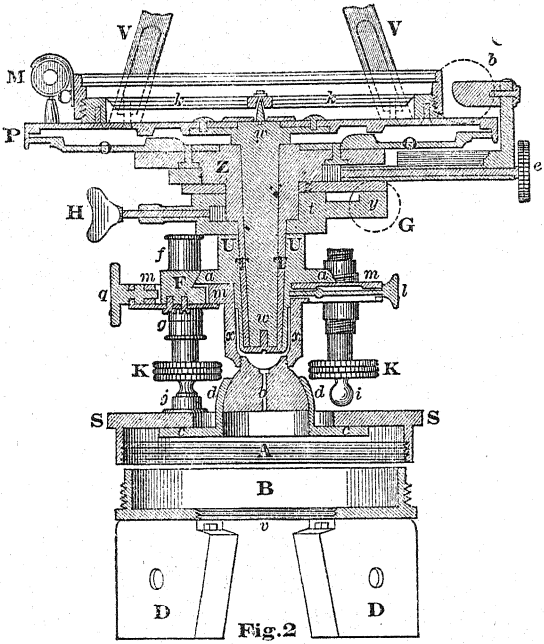

Fig.2

facilidad que por el método antiguo de enterrar un poco más en el suelo una ó dos de las patas ó abrirlas más ó menos. Hecho esto se aprietan los tornillos K, con lo cual se empuja hacia arriba la **placa paralela superior** *mmmxx*, y con ella la media bola *b;* apretando así á *cc* contra la cara inferior de S. El hilo de la plomada pasa por el agujero vertical *b*. Los tornillos niveladores están protegidos del polvo por casquetes *f*, *g*. Las patas *i* de los tornillos, se mueven en cubos ó muñoneras sueltas *j*, que tienen plana la cara que se apoya en la placa S, para que no se gaste con el roce. Las piezas descriptas hasta ahora se dejan generalmente unidas á la trípode. La fig. 1 muestra el modo de unirlas.

**Colocación de la parte superior del instrumento sobre las placas paralelas.** Póngase el extremo inferior de UU en *xx*, sosteniendo el instrumento en una posición tal, que los tres bloques *mm* (de los cuales el que se muestra en F es movible) puedan entrar en las tres escopladuras correspon

dientes *a*, permitiendo de este modo que éstas se apoyen perfectamente en *m*, donde descansa entonces la parte superior del instrumento. (La punta interior del resorte de presión *l*, penetra mientras tanto en una ranura que está alrededor de U, justamente debajo de *a*, é impide que se caiga la parte superior cuando el instrumento se transporta al hombro.) Comuníquesele á dicha parte superior un movimiento horizontal muy pequeño en una ú otra dirección hasta que se detenga al tropezar una pequeña pestaña ó uña que tiene en *a*, contra uno de los bloques F. Las cavidades ó escopladuras *a*, están ahora libres de los bloques. Apriétese á *q* con lo cual se empuja hacia adentro el bloque movible F, que aprisiona la pestaña en bisel *a* entre él y los dos bloques fijos en *mm* y sujeta al eje U á las placas paralelas fijas. Permanece dicha pestaña sujeta de este modo durante el uso del instrumento.

**Para separar la parte superior del instrumento de las placas paralelas.** Aflójese á *q*, llévense las cavidades ó escopladuras *a* frente á los bloques F. Reténgase á *l* y levántese la parte superior del instrumento, que se halla ahora sujeta por la cabeza ancha del tornillo colocado entre el pie del eje *w*.

TT es el **eje exterior giratorio** fundido en una sola pieza con la **placa de soporte** ZZ, á la cual está fijo el **limbo graduado** OO. Este limbo sobresale á la caja de la brújula, permitiendo así graduaciones mayores; *ww* es el **eje giratorio interior.** En su parte superior tiene un ancho reborde al cual está fijo el **nonio** P. A aquél está sujeta **la caja de la brújula** C, los **tubos de burbujas** MM y los **soportes** VV que sostienen el anteojo, etc. Cada tubo de burbuja está sostenido y ajustado por dos tornillos situados uno en cada extremo. La tira doblada que se encorva sobre el tubo protege el vidrio.

**Movimiento del limbo graduado** OO **y del disco del nonio** P. El tornillo tangencial G y un resorte espiral (que no se ve) opuesto á él, están fijos al limbo graduado OO y tienen entre ellos una proyección *y* del collar *t*, que está así ligado al limbo y se mueve con él. El tornillo H pasa por el collar *t* y comprime la pieccita que se ve en su extremo en el interior. Cuando se aprieta H, esta pieccita comprime el eje UU, al cual queda así fijado el limbo graduado. Sólo se le puede dar un pequeño movimiento al limbo por medio del tornillo tangencial G.

El movimiento del nonio P sobre el disco graduado OO se da de un modo análogo por el tornillo tangencial *b* y su resorte espiral (no visible) fijo al disco del nonio P y por el tornillo de presión *e* que pasa por el collar Z y comprime la pieccita que se ve en el interior y en su extremo de modo análogo al H. En los instrumentos de Heller y Brightly, el tornillo *b* está provisto de los medios de recuperar el movimiento perdido, ó en otros términos, llegado al fin de su carrera, puede recomenzarla.

En el instrumento hay dos nonios; uno se ve en *p*, fig. 1. Ambos se deben leer, y tomarse el término medio de su lectura cuando se necesita una gran exactitud. Los reflectores de marfil *c* facilitan su lectura. Antes de mover el instrumento de un lugar á otro, la **aguja de la brújula** *k*, fig. 2, debe siempre apretarse contra la cubierta de vidrio de la caja de la brújula por medio del tornillo vertical de cabeza acordonada que se ve en la placa del nonio, fig. 1, justamente á la derecha del pie del soporte. La punta del estilo está así á cubierto de cualquier daño.

R, en la fig. 1, es un anillo provisto de un gancho ó abrazadera (este último no se ve) para sostener el anteojo en cualquiera posición que se desee. Es mejor dejar que la extremidad *ocular* E del anteojo gire hacia *abajo*, porque de lo contrario la tapa en O puede caerse si está puesta. El tornillo tangencial *d* mueve un brazo vertical fijo en R, y se usa para variar ligeramente la elevación del anteojo. En el brazo tapado en la figura hay una rendija semejante á la que se ve en el brazo del nonio *l*.

Cuando se coloca el 0° del nonio en la división que señala 30° del arco *g* y se sitúa el índice del brazo opuesto sobre una pequeña ranura que tiene la abrazadera horizontal de los soportes (que no se ve en nuestras figuras), las dos rendijas estarán opuestas la una á la otra, y pueden usarse para fijar puntos en ángulo recto á la línea visual, sea como referencias ó con cualquier otro objeto. Un extremo R del eje del anteojo descansa en una caja movible debajo de la cual hay un tornillo. Por medio de este tornillo, la caja puede subirse ó bajarse, y ajustarse al eje del anteojo en caso de que haya cualquier pequeño desarreglo en los apoyos. Con respecto á E, B, O y A (véase Nivel, pág. 318), *a* es un estuche donde se mueve el objetivo.

**Pelos de la Estadia.** Inmediatamente detrás del tornillo *p*, fig. 1, [illegible]

otro tornillo más pequeño. Éste, y otro semejante que está del lado opuesto del anteojo, se mueven en un anillo en el interior de dicho anteojo, llamado retículo. y mantienen este anillo en su posición. A través del anillo están colocados otros dos pelos horizontales, llamados pelos de la Estadia, puestos á una distancia vertical tal, el uno del otro, que pueden abarcar 10 divisiones de una mira graduada colocada á 100 metros (por ej.) de distancia del instrumento, 15 divisiones, á 150, etc. Se usan para medir distancias horizontales é inclinadas.

(*Obs. del T.*— En el sistema métrico es muy práctico separar los pelos de manera que á 100 metros de distancia abarquen un metro en la mira y así en proporción : un decímetro para 10 metros, etc.)

**El tubo largo de burbuja** FF, fig. 1, nos permite emplear el tránsito como nivel, aunque no se presta tan bien como este último para tal uso *.

## Corrección de un tránsito común.

Cuando se compra un nivel ó un tránsito, es una buena precaución (pero que el autor nunca ha visto mencionada) llevar á su lugar el objetivo por medio de su tornillo hasta que esté bien apretado; y hacer entonces una corta raya continua en el anillo del objetivo y sobre la corredera del lente; de tal modo que se pueda ver en cualquier momento, cuando se está trabajando, si el lente se conserva en la misma posición con respecto á su corredera. Porque, si después de terminar todas las correcciones del instrumento, la posición del lente cambia (como es fácil que suceda si se desatornilla y luego no se atornilla de nuevo exactamente como antes lo estaba), entonces pueden ser inútiles todas las correcciones, especialmente si el lente del objetivo es excéntrico, ó si no está hecho con toda exactitud, como resulta muchas veces. El fabricante debe preparar dichas marcas. Al hacer las correcciones, así como al hacer uso de un tránsito ó de un nivel, téngase cuidado de que el ocular y el objetivo estén en una posición tal, *que no haya paralaje.* (*N. del T.* — Es decir, sin que se note un movimiento aparente alrededor de los pelos, cuando se mueve el ojo un poco hacia arriba ó hacia abajo ó lateralmente.) El ocular debe sacarse primeramente lo necesario para ver con mucha claridad los pelos que se cruzan; conseguido esto, no debe moverse sino el objetivo para ver á diferentes distancias.

**Primero. Averiguar si los niveles de aire, MM, son paralelos á la placa del nonio,** y *si en consecuencia, cuando ambas burbujas están en el centro de sus tubos, el eje del instrumento está vertical.* Por medio de los cuatro tornillos de nivelar, K, tráiganse ambas burbujas á los centros de sus tubos respectivos en una posición cualquiera del instrumento, luego désele *media vuelta* á la parte superior del instrumento. Si las burbujas no permanecen en el centro, corríjase la *mitad* del error por medio de los dos tornillos *rr* y la otra mitad por medio de los tornillos de nivelar K. Repítase el ensayo hasta que ambas burbujas se queden en el centro, mientras se le da una vuelta entera al instrumento sobre su eje.

**Segundo. Ver si los parales ó soportes han sufrido algún desarreglo;** es decir, si tienen igual altura y están colocados perpendicularmente á la placa del nonio, como lo están siempre cuando salen de la fábrica.

Póngase el instrumento perfectamente á nivel, luego diríjase la intersección de los pelos á cualquier punto de un objeto elevado (como la punta de una torre) que no esté muy distante; fíjese el instrumento por medio de los tornillos H y *e* y bájese el anteojo hasta que la intersección encuentre algún punto de un objeto bajo (si no hay ninguno, clávese una estaca ó aguja). Luego afílojese á H ó á *e* y désele media vuelta á la parte superior del instrumento; llévese otra vez la intersección sobre el punto alto; fíjese el instrumento y llévese el anteojo al punto bajo.

Si la intersección de los pelos encuentra otra vez al punto bajo, los parales ó soportes estarán bien. Si no, corríjase *la mitad* de la diferencia por medio de los bloques ó cojinetes de ajuste y del tornillo R que está en el extremo del eje de suspensión del anteojo, fig. 1, y repítase el ensayo de nuevo, cambiando el lugar de la estaca ó de la aguja en cada ensayo. Si el eje del instrumento carece de bloque de ajuste, devuélvase al fabricante para que corrija cualquier desarreglo que tengan los soportes.

* *N. del T.* — Esta minuciosa descripción no sirve sin duda (como lo dijo el autor para tránsitos de otros fabricantes, porque de unos á otros hay notables diferencias de estructura; sin embargo hemos dejado ésta, como un ejemplo que da á conocer esta clase de instrumentos.

El tránsito puede usarse *para trazar líneas rectas*, aun cuando los soportes estuviesen ligeramente doblados, por el procedimiento descrito al fin de la cuarta corrección.

**Tercero. Observar si los pelos transversales permanecen verdaderamente verticales y horizontales** cuando el instrumento está á nivel. Cuando el anteojo da imágenes invertidas, los pelos transversales están más cerca del ocular que cuando da las imágenes en su posición real. El fabricante tiene cuidado de colocar los pelos en ángulo recto en el anillo ó diafragma llamado retículo; y generalmente coloca el anillo en el anteojo, de manera que estando éste á nivel, aquéllos estén vertical uno y horizontal el otro. Algunas veces, sin embargo, se descuidan en este particular, ó el retículo puede girar un poco por cualquier accidente. Para cerciorarse de que uno de los pelos está vertical (en cuyo caso el otro debe estar, por construcción, horizontal), después de haber ajustado los niveles de aire póngase el instrumento cuidadosamente á nivel y diríjase una visual con el anteojo á una plomada ú otra línea vertical. Si el pelo vertical coincide con este objeto, estará bien, pero si no coincide, entonces aflójense *ligeramente* dos tornillos adyacentes *solamente*, de los cuatro *ppii*, fig. 1, y con una navaja, llave ó cualquier pequeño instrumento, golpéese suavemente contra las cabezas de los tornillos para hacer girar un poco el retículo entre el anteojo, hasta que el pelo esté vertical. Cuando se haya hecho esto, apriétense los tornillos.

Cuando no se tenga una plomada, ó regla vertical, diríjase el pelo á un punto claro muy pequeño, y véase si el pelo continúa sobre el mismo punto, bajando ó alzando el anteojo alrededor de su eje transversal.

El modo de hacer lo dicho se comprenderá prontamente con esta figura que representa una sección transversal de la parte superior del anteojo con los pelos transversales; *a* es el anillo de los pelos ,ó retículo; *v* el pelo vertical; *g* el tubo

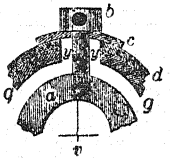

Fig. 3.

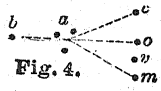

Fig. 4.

del anteojo; *d* el anillo exterior del tubo del anteojo; *b* es la cabeza de uno de los cuatro tornillos que mantienen en su puesto al retículo *a* y que sirven también para ajustarlo. Las puntas interiores de estos tornillos obran en el espesor del retículo, de modo que cuando se los afloja un poco siempre sostienen el anillo. Debajo de la cabeza *b* de los tornillos hay unas arandelas pequeñas sueltas *c*. Se deja un espacio *yy* alrededor de cada tornillo, en donde atraviesan el tubo del anteojo, para permitir que se muevan un poco, transversalmente, los tornillos y el anillo, cuando se aflojan ligeramente aquéllos.

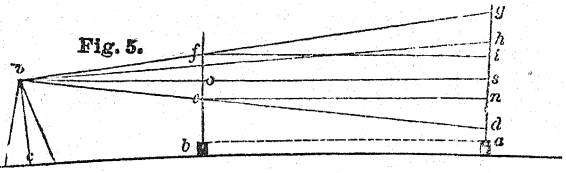
**Cuarto. Ver si el pelo vertical está en el eje de colimación.** Colóquese la trípode firmemente en el suelo como en *a*, fig. 4. Póngase el instrumento á nivel, sujétese y diríjase el pelo vertical por medio de los tornillos tangenciales G (figs. 1 y 2) hacia un objeto conveniente *b*, y si no existe ninguno, clávese una estaca delgada ó una aguja. Luego, haciendo girar el anteojo verticalmente sobre su eje, obsérvese un objeto cualquiera *c*. que encuentre el pelo vertical, y si no lo hubiere, colóquese una segunda aguja. Aflójese el instrumento por medio del tornillo H, y hágase girar toda su parte superior hasta que el pelo vertical encuentre otra vez á *b*. Fíjese el instrumento nuevamente y hágase girar otra vez el anteojo verticalmente sobre su eje. Si el pelo vertical encuentra ahora á *c*, como antes, es prueba de que *c* está verdaderamente en *o*, y de que *b*, *a*, *c* **están en la misma línea recta** y por consiguiente en este sentido está bien el instrumento. En el caso contrario, obsérvese donde encuentra por ejemplo á *m* (tomándose la distancia *am* igual á *ac*), y colóquese allí también una aguja. Mídase *mc*, y colóquese una aguja en *v*, en la línea *mc*, haciendo $mv = \frac{1}{4} mc$. Colóquese también una aguja en *o* entre *m* y *c*, en dirección de *ab*. Por medio de los dos tornillos horizontales que mueven el retículo ajústese el pelo vertical

hasta que encuentre á *v*. Repítase de nuevo *toda* la operación, y prosígase hasta que el anteojo después de haberse dirigido hacia *b* encuentre al mismo objeto *o* cuando el anteojo se haga girar sobre su eje. Obsérvese si el movimiento del retículo ha cambiado la verticalidad del pelo en esta cuarta corrección, y si así fuere, repítase la corrección tercera. Después repítase otra vez la cuarta si fuere necesario, y sígase haciendo así hasta que ambas correcciones estén perfectas al mismo tiempo. De este modo puede trazarse una línea recta aun cuando los pelos no estuviesen corregidos; pero con mucho más trabajo. Porque en cada estación como *a*, habrá que dirigir dos visuales, *ac*, *am*, y tomar el medio entre *c* y *m* que estará en línea recta con *ab*. Entonces se puede trasladar el instrumento á *o* y así continuar.

Los *ángulos* medidos por el tránsito, sean horizontales ó verticales, no resultarán afectados por la no corrección de los pelos con tal que haya un pelo vertical, ó que usemos la *intersección* de los pelos al medirlos.

**Las correcciones que anteceden son las únicas que se requieren**, á menos que el instrumento se necesite para nivelar; porque en este caso debe atenderse á lo que sigue.

**Para corregir el tubo largo del nivel de aire** FF, fig. 1, primeramente colocaremos la visual del anteojo horizontal, y luego haremos que el tubo del nivel esté también horizontal, de manera que los dos estén paralelos. Al efecto



clávense dos estacas *a*, *b*, fig. 5, con sus cabezas exactamente á nivel y por lo menos á una distancia como de cien metros una de otra.

Colóquese el instrumento firmemente en la dirección de dichas estacas, como en *c*, haciendo á *bc*, una parte alícuota de *ab*, tan corta como lo permita el anteojo. No es necesario que el instrumento esté á nivel, sino que tal como lo instalemos dirijamos una visual que supondremos pasar por *e* y *d*. Tómense las lecturas *b* y *ad*. Su diferencia es : $be - ad = an - ad = dn$; y $ab : ac :: dn : ds$; siendo *s* la altura de la tablilla ó corredera de la mira en *a*, cuando las lecturas (*as*, *bo*) hechas sobre las dos estacas son iguales. $as = ad + ds = ad + \frac{dn \times ac}{ab}$.

Si la lectura de la mira en *a* *excede* á la de la mira en *b* (como cuando la visual es *vfg*), la diferencia de lectura será $= ag - bf = ag - ai = gi$; y $as = ag - gs = ag - \frac{gi \times ac}{ab}$.

Conociendo á $as = ob$ diríjase la visual á *s*, la cual quedará situada horizontalmente, y llévese la burbuja al centro del tubo por medio de las dos tuercas pequeñas *nn* situadas en un extremo del tubo, fig. 1, y tendremos el anteojo y el tubo paralelos *.

Los ceros del círculo vertical y de su nonio, pueden ahora arreglarse, si fuere necesario, aflojando los tornillos del nonio y moviéndolos luego hasta que coincidan los dos ceros.

**Nota.** Si no hay á la mano un nivel para nivelar las dos estacas, puede hacerse

---

* Aquí no se toma en cuenta el pequeñísimo error debido á la curvatura de la tierra porque la línea *horizontal* en *v* es *vh*, y representa la tangente á la superficie curva (ó «nivel») del agua en equilibrio en *v*; mientras que *vs* representa la tangente á la superficie del agua en un punto intermedio entre *a* y *b*. Por consiguiente si el anteojo en *v* se dirige á *s* no será paralelo el eje del nivel. Tomando en cuenta esto y la refracción del aire *que disminuye* el error, súbase la corredera ó tablilla á un punto *h* más arriba de *s*, de modo que *hs* será $= .0000000205 \times$ cuadrado de *ac* en pies, pero cuando *ac* sea igual á 650 pies, *hs* será solamente como un décimo de pulgada, y apenas cubrirá el espesor aparente del pelo transversal del anteojo.

** *N. del T.* —Para usar esta fórmula en el sistema métrico : *hs* en m $= .0000000672 \times ac$ elevado al cuadrado (en metros). Para una distancia *ac* de 200 metros, *hs* será solamente de 2.7 mm.

con el mismo tránsito de la manera siguiente : Póngase cuidadosamente á nivel los dos niveles pequeños de aire, por medio de los tornillos de nivelar K. Clávese una estaca *m* á una distancia de 30 á 100 metros del instrumento *o*. Colocando

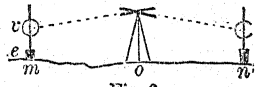


**Fig. 6.**

entonces en *m* una mira de corredera ó tablilla, fíjese ésta á cualquiera altura *ev*, en que la intersecte el pelo horizontal; no importa que el anteojo esté á nivel ó no, aunque sería mejor ponerlo lo más horizontal posible á la vista. Fíjese el anteojo por medio del anillo R, fig. 1. Hágase girar el instrumento alrededor de su eje vertical un espacio considerable, como, por ejemplo, media vuelta ó cerca de media vuelta; colóquese otra estaca *n*, *á la misma distancia precisamente que está m* del instrumento y sígase clavando la estaca, hasta que el pelo horizontal intersecte la tablilla de la mira puesta sobre ella y fija todavía á dicha mira á misma altura que tenía en *m*. Hecho esto, las cabezas de las estacas estarán á nivel, y en disposición de usarlas como anteriormente. Cuando se trata de usar un tránsito para deslindar ó levantar planos de haciendas, etc., ó para trazar de nuevo las líneas de una mensura antigua, es muy útil arreglar la brújula de modo que se puedan apreciar las variaciones de declinación del meridiano magnético durante el tiempo transcurrido entre los dos levantamientos. Para este objeto, se agrega **un nonio de declinación** á dicho tránsito, y también á la brújula Cuando la graduación del tránsito está numerada de tal manera que se puede leer á ambos lados del cero, como se ve en la figura, se hace el nonio doble

también; es decir, que se gradúa y numera de modo, que pueda leerse del cero á derecha é izquierda de éste. En este caso, si se mide el ángulo del cero á la derecha, la lectura debe hacerse en la parte del nonio que está á la derecha del cero, y viceversa. Si la numeración es sencilla ó en una dirección solamente, de cero á 360°, entonces no se necesita sino un nonio sencillo, porque los ángulos se miden solamente en la dirección de la numeración. Los ingenieros tienen diferentes opiniones sobre la preferencia que se debe dar á estos modos de numerar las graduaciones. El autor prefiere la numeración de cero á 180° en ambos sentidos con dos nonios dobles.

**Reposición de los pelos en un nivel ó tránsito.** Sáquese el tubo de la extremidad ocular del anteojo. Obsérvese y anótese cuál lado del retículo está hacia el extremo ocular. Luego aflójense los cuatro tornillos que sostienen el diafragma ó retículo de modo que puedan sacarse del anteojo. Fíjense nuevos pelos con cera, barniz, cola ó goma, etc. Esta operación requiere mucho cuidado. Para volver el diafragma á su lugar, colóquese firmemente, en uno de los agujeros de los tornillos que están en la circunferencia del mismo diafragma, la punta de una astillita de madera, de suficiente largo para que llegue fácilmente hasta dentro del anteojo al lugar que ocupa el diafragma. Por medio de esta astilla á manera de mango, colóquese el diafragma de canto en su puesto en el anteojo y sosténgase así hasta que los dos tornillos *opuestos* se hallen colocados en su lugar y estén atornillados. Sáquese entonces la punta ó astilla del agujero del diafragma y con el mismo hágase girar éste hasta que la misma cara, que estaba antes hacia el ocular, vuelva á estar de la misma manera; y después colóquense los otros dos tornillos.

Los así llamados pelos cruzados son de tela de araña, tan finos que apenas son visibles á la simple vista. Los señores Heller y Brightly usan hilos de platino muy finos, que son mucho mejores. El cabello es demasiado grueso.

**Reposición del tubo de vidrio de un nivel de aire.** Quítese el nivel del instrumento; sáquense sus extremos de correderas; empújese hacia fuera el tubo de vidrio roto y la substancia con que está adherido, colóquese el tubo nuevo con el lado que corresponde hacia arriba (que siempre está marcado con una lima por el fabricante), envolviendo sus extremos con papel, si quedan flojos. Finalmente, póngase un poco de pasta ó cera derretida en las puntas del tubo de vidrio para evitar que se mueva en el tubo del nivel.

Al comprar instrumentos, especialmente cuando han de usarse lejos de la fábrica, es conveniente proveerse de repuestos de las piezas que puedan romperse ó perderse fácilmente, tales como las tapas de vidrio de la brújula, agujas, llaves para apretar los tornillos, tubos de burbujas, lentes de aumento, etc.

Las correcciones de un **teodolito** se hacen lo mismo que las del nivel y de tránsito :

1.° La de los pelos que se cruzan; lo mismo que en el nivel.

2.° La del nivel del anteojo; también como en el nivel.

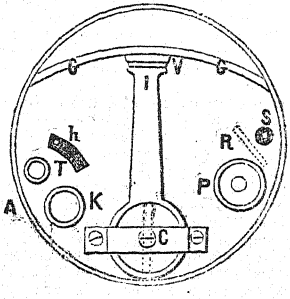
3.° La de los dos niveles pequeños; lo mismo que en el tránsito.

4.° El nonio del círculo vertical; lo mismo que en el tránsito de círculo vertical.

5.° Para ver si el pelo vertical se mueve verticalmente lo mismo que en la cuarta corrección del tránsito. Algunos teodolitos no están provistos de medios para hacer esta corrección; pero á los grandes se les provee de tornillos debajo de los pies de los apoyos. Algunas veces se agrega un segundo anteojo, bajo el limbo horizontal, con sus abrazaderas y tornillo tangencial propios. Se emplea para averiguar si el cero del limbo graduado se ha movido durante la medida de los ángulos horizontales. Cuando antes de principiar la medida el cero y el anteojo superior están dirigidos hacia el primer punto, diríjase el anteojo inferior hacia cualquier objeto pequeño distante y fíjesele. Durante las medidas subsiguientes, obsérvese de vez en cuando por él, para asegurarse de si todavía intersecta el mismo objeto, probando de este modo que no ha ocurrido movimiento alguno.

# SEXTANTE DE CAJA O DE BOLSILLO

La facilidad con que se lleva un sextante de bolsillo, y el hecho de que se aprecien en él hasta minutos, lo hace algunas veces muy útil al ingeniero. Con él podemos medir ángulos desde un bote ó á caballo; y en muchos casos donde no es posible el empleo de un tránsito. Por medio de un horizonte artificial es muy



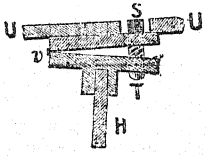
fácil obtener latitudes. Cerrado, parece una caja cilíndrica de cobre de tres pulgadas de diámetro (8 cm) más ó menos y de 1½ pulg (4 cm) de alto. La caja se compone de dos partes que desatornillándolas é invirtiendo una de ellas y atornillándola otra vez, la parte inferior sirve de mango para agarrar el instrumento. Mirándola de arriba hacia abajo después de arreglada así, observamos, como en la figura, un brazo movible IC, llamado **índice**, que gira alrededor de un centro C, y tiene un nonio V en el otro extremo; GG es un arco graduado ó **limbo**. El arco tiene una amplitud de 73°; pero está dividido en 146°. Su cero está en una extremidad. No se ven las graduaciones en la figura.

Adherida al índice hay una pequeña lente movible (que no se ve en la figura), la cual gira también alrededor de C, para leer las graduaciones pequeñas del limbo. Para medir un ángulo, se mueve el índice dándole vueltas á la cabeza acordonada del piñón P, que actúa en una cremallera colocada en el interior de la caja. El ojo

se aplica á una abertura circular que está á un lado de la caja cerca de A. Un pequeño anteojo, de 8 cm más ó menos de largo, acompaña al instrumento, pero generalmente no es necesario. Cuando se usa sin el anteojo, el hueco destinado al ojo en A, debe cerrarse parcialmente por medio de una corredera, que tiene un agujero muy pequeño para aplicar el ojo y que se mueve por medio de una clavija *h* en una ranura curva. Otra corredera ó anillo movible, que se halla á un lado de la caja, está provisto de un vidrio obscuro para cuando se observa el sol. Cuando se usa el anteojo se fija por medio del tornillo de cabeza acordonada T. La parte superior que se muestra en nuestra figura, puede separarse de la parte cilíndrica, sacando 3 ó 4 tornillitos que tiene en el borde; y entonces puede examinarse el interior y limpiarse si se desea. Como los sextantes náuticos y otros, éste tiene dos vidrios principales, ambos azogados ó reflectores. El uno, el **espejo central**, está fijo á la parte inferior del índice en C cuyo borde superior está representado por las líneas de puntos.

El otro, llamado **espejo de horizonte** (porque cuando se miden ángulos verticales de cuerpos celestes se dirige hacia el horizonte), se halla también en el interior de la caja, y la posición de su borde superior está indicada por la línea de puntos en R. El espejo del horizonte está azogado solamente en su mitad superior; de manera que uno de los objetos observados puede verse directamente á través de su parte inferior, mientras que la imágen del otro objeto se ve en la parte superior, reflejada por el espejo central ó espejo del índice. Para que el instrumento esté correcto y en disposición de usarlo, estos dos espejos deben ser perpendiculares al plano del instrumento; esto es, á la cara á que están fijos y paralelos entre sí cuando el cero del limbo coincide con el cero del nonio.

El espejo central ha sido fijado de antemano y de modo permanente por el fabricante y no requiere ninguna otra corrección; pero al horizontal hay que hacerle dos correcciones, por medio de una llave semejante á una llave de reloj, de cabeza cordonada. Está atornillada en la tapa de la caja, para tenerla siempre á la mano. Cuando es necesario, se desatornilla. Esta llave ajusta en dos cabezas cuadradas pequeñas (como algunas llaves de relojes), una de las cuales se ve en S, mientras que la otra está cerca de S, pero al lado de la caja. Estos cuadrados son las cabezas de dos tornillos pequeños. Si el espejo del horizonte H no estuviese como en el



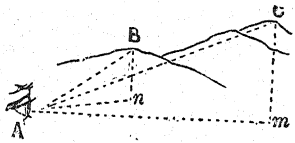
diseño (donde se ve de canto), en ángulo recto á la tapa UU de la caja, se puede arreglar dándole vuelta á la cabeza cuadrada S del tornillo ST; y si después de estar rectificado así no está aún paralelo al espejo central, cuando coinciden los ceros, entonces se le mueve un poco hacia adelante ó hacia atrás por medio de la cabeza cuadrada del tornillo del lado.

**Para corregir un sextante de bolsillo**; háganse coincidir exactamente los dos ceros; luego mírese por el agujero destinado al ojo y por la parte baja ó sin azogue del espejo del horizonte, un objeto distante. Si el instrumento está arreglado, el objeto visto así directamente coincidirá exactamente con su imagen reflejada vista al mismo tiempo y en el mismo lugar. Pero si no lo está, los dos objetos aparecerán separados horizontal ó verticalmente, ó de ambos modos, así: ⁂; en cuyo caso aplíquese la llave K á la cabeza cuadrada S; y haciéndola girar suavemente en cualquier dirección que sea necesario (*viéndose siempre el objeto y su imagen*) llévense á ambos á una posición horizontal, ó al mismo nivel, así: **. Luego aplíquese la llave á la cabeza cuadrada del lado de la caja y, dándole vueltas suavemente, háganse coincidir las dos imágenes perfectamente. Entonces el instrumento quedará corregido.

En algunos instrumentos, el espejo horizontal tiene una *visagra* en *v*, que le permite cierto juego durante el ajuste con el solo tornillo ST; pero otros no tienen esta visagra, sino *dos* tornillos semejantes á S en la parte superior de la caja además del que tienen al lado.

Si se emplea el sextante para medir ángulos verticales por medio de un **hori-**

**zonte artificial**, la altura verdadera no es sino la mitad de la que se lee en el limbo; porque entonces leemos al mismo tiempo el ángulo real y el ángulo reflejado. El gran inconveniente que presenta el sextante para los trabajos de ingeniería, es que no mide los ángulos horizontalmente, como lo hace el tránsito, á menos que el observador y los dos objetos se hallen en el mismo plano horizontal. De este modo, situado un observador con un sextante en A, para medir el ángulo



que forma este punto con la cima de los cerros B y C, deben mantener el plano graduado del sextante en el plano ABC; y realmente medir el ángulo BAC, en tanto que lo que necesita es el ángulo horizontal *nAm* proyección del BAC. Este ángulo es mayor que el BAC, porque las dist *An* y *Am* son más cortas que AB y AC. El tránsito nos da el ángulo horizontal *nAm*, porque el círculo graduado se pone de antemano horizontal con los tornillos de nivelar; y la medida del ángulo no se afecta porque se dirija la visual hacia arriba, sobre B y C. Para más detalles sobre esta materia, véase la nota del ejemplo 2, caso 4 de la « Trigonometría ».

**El sextante náutico**, usado á bordo, está construído sobre el mismo principio del sextante de bolsillo; y sus correcciones son muy semejantes. En él el espejo central ó espejo del índice está también fijo, una vez por todas, por el fabricante; y el espejo horizontal tiene las dos correcciones del sextante de bolsillo. También tiene vidrios obscuros para mirar el sol y un pequeño agujero para dirigir visuales cuando no se emplea el anteojo.

# LA BRÚJULA

### Corrección de una brújula.

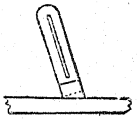
**La primera corrección** es la de los niveles. Colóquese firmemente el instrumento en el suelo y póngasele horizontal en cualquier posición, es decir, llévense las burbujas á los centros de sus tubos respectivos. Luego, désele media vuelta al instrumento. Si las burbujas permanecen en el centro, están correctas, pero si no, corríjase la *mitad* de la dif de cada burbuja por medio de los tornillos de los tubos. Póngase el instrumento otra vez horizontal, désele media vuelta; y si las burbujas no permanecen aún en el centro, hay que mover otra vez un poco los tornillos hasta rectificar la mitad de la dif que haya todavía. Generalmente tienen que hacerse varios tanteos de esta manera, hasta que las burbujas se mantengan en el centro, al darle una vuelta entera á la brújula.

**Segunda corrección.** Póngase horizontal la brújula y véase luego si la aguja está horizontal, y si no lo está, póngasele horizontal por medio de un pedacito de alambre fino que se arrolla alrededor de ella, y se desliza hacia su punta elevada. Una aguja arreglada de este modo, es decir, horizontal en un lugar, no se mantiene así si se la transporta hacia el norte ó hacia el sur de dicho lugar. Si se la lleva hacia el norte, la punta norte bajará; si hacia el sur, descenderá la punta sur. El alambre se usa para contrarresta reste movimiento.

**Tercera corrección.** Las pínulas por donde se dirigen las visuales se colocan en ángulo recto á la plancha de la brújula, de manera que cuando ésta está horizontal las pínulas están verticales. El fabricante siempre las fija correctamente. Para cerciorarse si esto es así, cuélguese una plomada, y habiendo nivelado la brújula, diríjasele una visual y obsérvese si las pínulas coinciden con el hilo de la plomada. Si una ó ambas hendiduras no coinciden, como se observa en este diseño exagerado, deben desatornillarse de la brújula y gastar un poco el pie por medio de una línea ó piedra de amolar como lo indica la línea de puntos. Como medio

provisional, puede ponerse una cuña pequeña debajo de la punta más baja, para levantarla.

**Cuarta corrección.** Para enderezar la aguja, si se hubiere doblado. Estando la brújula á nivel y la aguja horizontal floja en el estilo, obsérvese si los dos extremos continúan marcando graduaciones exactamente opuestas (es decir, gra-



duaciones con 180° de diferencia cuando se le ha dado una vuelta entera á la brújula). Si la aguja lo hace así, estará derecha, y el estilo en que se apoya estará en el centro del círculo graduado; pero si no, uno de los dos, ó ambos, necesitan corrección. Póngase primeramente el instrumento horizontal, luego hágasele girar hasta que una graduación cualquiera (por ejemplo 90°) coincida exactamente con la punta norte de la aguja; si la punta sur no señala ahora exactamente la graduación opuesta á 90°, levántese la aguja, y dóblese *la punta del estilo* hasta que aquélla se dirija al punto deseado, teniendo presente que, cada vez que se doble la punta, se debe hacer girar un poco el instrumento para conservar siempre la punta *norte* en los 90°. Entonces désele media vuelta á la brújula hasta que los 90° *opuestos* lleguen exactamente á la punta *norte* de la aguja. Hágase una marca fina de lápiz en el lugar donde está la punta sur de la aguja actualmente. Luego, levántese ésta, y dóblese hasta que la punta sur señale exactamente la *mitad* de la distancia comprendida entre los 90° y la marca de lápiz, cuando su punta norte se mantiene en los 90° moviendo la brújula un poquito (el grueso de un pelo). Entonces la aguja estará derecha; y no debe alterarse al hacer la corrección que sigue, aunque todavía no marque con toda exactitud los grados opuestos.

**Quinta corrección.** *Corrección del estilo.* Después de estar cierto de que la aguja está derecha, hágase girar la brújula hasta que se llegue á un punto en que los extremos de la aguja marquen divisiones diametralmente opuestas; luego hágase girar la brújula 90°. Si la aguja aún señala divisiones opuestas, la punta del estilo estará bien; pero si la aguja no señala dichas divisiones, dóblese la *punta del estilo* hasta lograrlo. Repítase la operación hasta que la aguja marque siempre grados diametralmente opuestos cuando se le dé una vuelta entera á la brújula.

Se necesita cuidado y esmero en las observaciones para hacer las correcciones con exactitud; porque todo error es generalmente una cantidad mínima, y el novicio es propenso á hacer más penosa la corrección por no saber usar el lente ó microscopio al observar la punta de la aguja y las graduaciones correspondientes. Debe tenerse el microscopio siempre con *su centro directamente sobre* el punto que se examina, y paralelo al círculo graduado. De lo contrario se cometerán errores perjudiciales hasta de algunos minutos en una sola observación; y la acumulación de dos ó tres de estos errores, producidos por una causa desconocida para él, pueden hacerlo abandonar las correcciones desesperadamente. Esta observación se aplica también á la lectura de ángulos tomados con el tránsito, etc., aunque los errores entonces no resultarán tan grandes como con la brújula. Al comprar un microscopio para una brújula, obsérvese que ninguna de las piezas, como visagras, remaches, sean de hierro, porque éstos influyen sobre la dirección de la aguja.

Si las pínulas de la brújula no están dispuestas por el fabricante de manera que estén en una misma línea con los ceros opuestos, el ingeniero no puede corregir este defecto. Para conocerlo se puede pasar un hilo fino por las hendeduras y observar si éste pasa naturalmente sobre los ceros.

(*Advertencia del Traductor.*— Aunque este mapa, y lo que se dice en seguida sobre la Declinación Magnética y sus variaciones, se refieren exclusivamente á los Estados Unidos, pueden servir algunas veces de enseñanza á los agrimensores ó ingenieros, y siempre de advertencia, para que indaguen y recojan en cada localidad donde hagan un levantamiento Topográfico ó Geodésico, los datos análogos, tan indispensables para lograr un plano ó carta que merezca fe. Además, la circunstancia de que éste, como otros muchos capítulos de grandísima utilidad, no están tratados en los otros formularios ó lo están rara vez y muy someramente, nos ha inducido á dejarlo.)

## DECLINACIONES Y VARIACIONES MAGNÉTICAS

Generalmente la aguja magnética no marca exactamente el meridiano astronómico; es decir, no está sobre la Norte-Sur. El ángulo que ella forma con esta línea se llama **declinación magnética.** La declinación magnética es distinta (á una hora dada) en los diversos lugares, y en un mismo lugar varía con el tiempo. Estos cambios se llaman **variación magnética.**

### Variaciones según los lugares.

Además de las perturbaciones locales, como las debidas á la influencia del hierro en el suelo, ó en las minas, el cascajo ferruginoso, las piedras volcánicas, etc., la declinación varía, de lugar á lugar, de acuerdo con las leyes generales del magnetismo terrestre. Así en los E. U. (véase al frente la carta * de líneas isogónicas) existe una línea donde no hay declinación, marcada 0°, que actualmente empieza en Michigan y termina en la Carolina del Sur. En puntos situados al Este de esta línea, la declinación es hacia el Oeste y viceversa; el valor de la declinación aumenta con la dist del punto á la línea; actualmente llega á 21° al Oeste en Maine, y 23° Este en el Estado de Wáshington. Las líneas que unen los puntos donde la declinación es la misma se llaman **líneas isogónicas.** Los lugares donde no se ha podido determinar con exactitud esta línea están indicados con puntos suspensivos.

### Variaciones con el tiempo.

**Variaciones seculares†.** Actualmente, en cualquier punto de los E. U. la declinación va aumentando hacia el Oeste (las declinaciones al Oeste aumentan y las al Este decrecen) á razón de 1 á 5 minutos por año. Ésta se llama **variacion secular,** y su valor en un año es la **variación anual.** La carta señala con líneas en contorno y de puntos los lugares de igual **variación anual,** de 1′ á 5′, y éstas generalmente cortan á las líneas isogónicas casi en ángulo recto. Más allá de los límites de la carta, á ambos lados, se encuentran las líneas donde no hay variación anual. A lo largo de esta línea, la declin oeste (en el Atlántico) y la declin este (en el Pacífico) han alcanzado su máximum y están retrogradando hacia el Este y el Oeste respectivamente. La variación secular imprime á la línea de declinación 0 (cero) y á la línea donde la variación anual es nula (ó sea de máxima declinación) un movimiento hacia el Oeste de unos 3 ó 4 minutos de longitud por año.

**Variación diurna.** En cualquier punto dado la aguja oscila, en un día alrededor de su posición media en un arco que llega á veces hasta 12′ ó 15′, alcanzando su distancia máxima al Este, de 8 á 8-30 A.M.; y la del Oeste de 1 h 15 m á 1 h 30 m P.M.; á la posición media, ó la normal diurna, llega generalmente de 10 h á 11 h 30 m A.M. y de 7 h á 8 h P.M.

Su máximum hacia el Este lo alcanza con media hora de anticipación en verano y media hora más tarde en invierno, y la del Oeste como $^1/_4$ de hora más temprano en verano y $^1/_4$ más tarde de invierno que en la época media.

El arco descrito entre las dos posiciones extremas Este y Oeste, ó sea de la mañana á la tarde, es la **variación diurna.** En Filadelfia, ésta varía de 5′ á mitad del invierno á 12′ en mitad del verano; en Key-West, de 3′ á 8′; en los Angeles de 4′ á 9′. En los años de menor actividad en las manchas solares, la variación es un 20% menor y de 30 % mayor en épocas de mucha actividad; todo esto con respecto al promedio. Pero la variación diurna es muy irregular, especialmente en las estaciones de mínimos.

**Otras variaciones.** La aguja también está sometida á pequeñas variaciones mensuales y anuales y á la influencia de las tempestades eléctricas, las que causan perturbaciones de 15′ y más en la posición normal de la aguja.

**Electricidad.** La electricidad, ya sea atmosférica ó producida por fricción en el cristal de la caja de la brújula, produce perturbaciones, las que se evitan tocando el vidrio con la lengua ó el dedo húmedos.

* Esta carta es la reducción de un gran mapa para 1902, publicado por la Oficina de estudios Geodésicos y de las costas de los E. U., basado en 4.700 observaciones, hechas y escogidas por los mejores observadores. En las regiones en que no se pudo determinar satisfactoriamente la posición de las líneas por aquellos medios, se usaron gran cantidad de datos compilados por H. Gannett.

† Secularó que comprende un dilatado período de tiempo.

### DESMAGNETIZACIÓN

Si la aguja está hecha de un metal blando, pierde á veces parte de su magnetismo y no funciona bien. Se la puede restaurar, friccionándola 10 ó 12 veces de su centro á la punta sur con el polo norte de un imán (en herradura ó recto). Después de cada pasada retírese el imán á unos 40 cm de la aguja y vuélvase á pasar comenzando siempre en el centro. Cada mitad de la aguja, á su turno, mientras se la está tratando así, debe mantenerse á plano sobre una superficie lisa y dura. La mayor parte de las dificultades que se observan en el funcionamiento de la aguja, se deben en gran parte al deterioro de la punta del estilo que la sostiene. La remagnetización desequilibra la aguja y esto se remedia con un anillito de alambre corredizo en la mitad levantada.

Para evitar errores por contar los ángulos, á veces desde un extremo de la aguja, á veces desde el otro, siempre se debe colocar el punto N de la caja hacia el objeto cuya direccion se determina, y luego leer desde el extremo norte de la aguja hacia un mismo lado siempre. Esto es también más exacto.

## CURVAS DE NIVEL

**Curva de nivel** es una línea curva horizontal cuyos puntos están al mismo nivel †.

Así pues, cada una de las curvas de nivel 88*c*, 91*c*, 94*c*, fig. 1, indica que cada uno de los puntos por donde están trazadas se hallan al mismo nivel y á la altura de 88, 91 ó 94 metros sobre otro plano á nivel *c* llamado plano de comparación, y al cual se refieren.

A menudo se supone el punto de partida con la cota O (*cero*) é imaginamos que pasa por él el plano de *comparación*, y si estamos seguros de no encontrar puntos más bajos, nos servirá para todas las operaciones; pero si hay la probabilidad de que hallemos otros más bajos aún, es mejor atribuirle al punto de partida una cota dada sobre un plano de comparación situado en un punto más bajo que aquéllos. El único objeto es evitar los errores que se pueden cometer al trabajar con cotas negativas y positivas al mismo tiempo. Para lo cual podemos suponer que el punto de partida tiene una cota de 10, 100, 1,000 metros sobre el plano indicado, según las circunstancias. Conforme á la definición, la dist vertical entre cada dos curvas de nivel se supone igual, y en levantamientos para ferrocarriles en terrenos bien conocidos, en que el ingeniero sabe que el trazado de su línea verdadera no ha de variar mucho, dicha dist puede ser de 1 metro solamente, no siendo necesario trazar curvas de nivel á más de 40 ó 50 metros á cada lado de las estacas de centro; pero en regiones cuya topografía es relativamente desconocida, y donde por esta razón pueden presentarse obstáculos insuperables, que exijan variaciones importantes desde atrás en el trazado y á considerable distancia, los estudios deben ser más amplios y la equidistancia de las curvas de 1 á 5 metros según la conformación del terreno. Cuando el levantamiento se hace para la formación del mapa topográfico de un Estado ó de un departamento, son suficientes equidistancias de 2 á 3 metros. Supongamos que la línea AB, fig. 1, que parte de O, represente tres estaciones (S 1, S 2, S 3) del trazado del eje de una línea férrea, y que los números 100, 103, 101, 104 indicados en ella, señalan las altúras de las estacas sobre el plano de comparación, tales como se determinaron en la nivelación.

Entonces el objeto de las curvas de nivel es estudiar en la oficina el efecto de la variación del eje del trazado AB, al mover cualquier parte de él hacia la derecha ó hacia la izquierda *. Así, por ejemplo, moviendo la línea AB 30 metros hacia la izquierda, el punto de partida O estaría en un punto del terreno más ó menos 6 metros más alto que ahora, porque su cota sería más ó menos 106 metros en lugar de 100. La estación 1 estaría más ó menos 7 metros más alta ó 110 metros en lugar de 103. La estación 2 estaría como á 7 metros más alta ó

† *N. del T.* — Se da el nombre de *curvas de nivel* á la intersección de la superficie del terreno con planos horizontales ó á nivel.

* Al usar las palabras derecha é izquierda, suponemos que tenemos el punto de partida del levantamiento á nuestra espalda. **La margen derecha de un río** es la que está á nuestra derecha, **descendiendo**, es decir, se supone que tenemos el lugar donde nace ó su origen á nuestra espalda.

108 metros en lugar de 101. Si la línea se tira hacia el lado derecho, cae en terreno más bajo.

Estas curvas de nivel se trazan algunas veces en el terreno con un nivel de aire, pero más frecuentemente con una regla recta graduada, de 4 metros de largo más ó menos y con un eclímetro.

En cada estación se coloca la regla en el suelo formando lo más posible al ojo ángulo recto con el eje AB, y colocando el eclímetro sobre la regla, se mide el

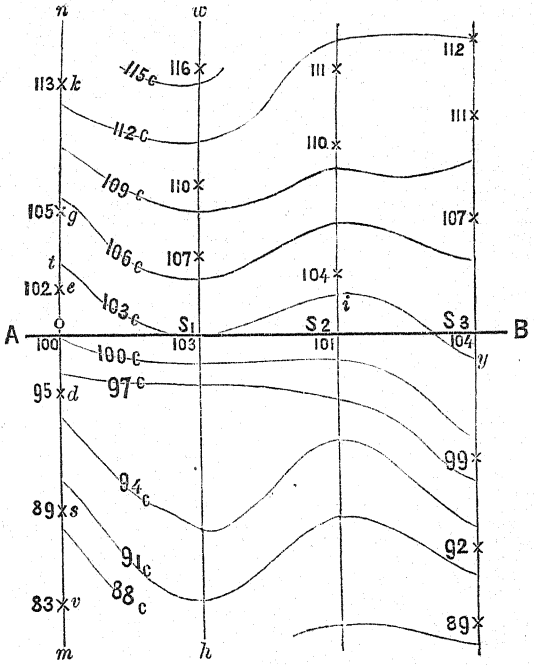

Fig. 1.

ángulo de inclinación del terreno con un cuarto de grado de aproximación. También se observa hasta qué distancia más allá de la regla continúa el terreno con la misma pendiente; y se mide esta distancia con ella. Luego poniendo la regla en este otro punto donde cambia la pendiente, se mide la inclinación que sigue lo mismo que su longitud; y se continúa así hasta donde se juzgue necesario. Estas notas se llevan en una cartera de apuntes (minuta), como se ve en la fig. 2; anotando los ángulos de inclinación sobre las líneas y las distancias debajo, todo acompañado de las observaciones que se ocurran, como indicar que hay bosques, rocas, arena, pantanos, sembrados jardines, ó bien donde se atraviesa un arroyo, etc., etc.

No es absolutamente necesario representar las pendientes en la libreta de apuntes, como en la fig. 2; porque usando el signo + para significar « ascenso », el — « descenso » y el = « al nivel », las pendientes pueden trazarse en línea recta, como en la figura 2½.

Habiendo recogido todos los datos y observaciones, el trazo de las curvas de nivel por medio de ellos es trabajo de oficina y se hace generalmente al mismo tiempo que el plano. Las observaciones del terreno, hechas en cada estación, se trazan luego

por separado por medio del transportador y en partes de la escala, como se muestra en la fig. 3, comenzado en el punto de partida O. La escala no debe ser menor de $^1/_{100}$, si se desea alguna exactitud. Suponiendo ahora que en dicha estación las pendientes

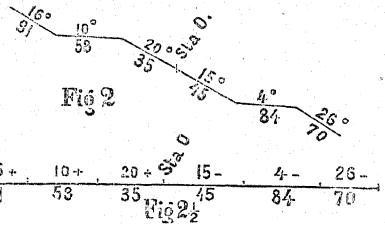

Fig 2

Fig 2½

hacia la derecha sean como en la fig. 2, de 15°, 4° y 26°, y las de la izquierda, de 20°, 10°, y 16°, y que las dist sean las de la misma figura. Trácese una línea horizontal *ho*, fig. 3, y supóngase que el centro sea la estaca donde se hizo estación. De este punto como centro, trácense estos ángulos con el transportador, como lo indican los arcos en la fig. 3. Luego principiando, por ejemplo, por el lado derecho, con una regla de trazar paralelas trácese la primera dist *ae* con su propia inclinación de 15.°, y su longitud por la escala. Luego lo mismo con *ey*, *yt*. Hágase del mismo modo con las inclinaciones y distancias del lado izquierdo.

Así tenemos una *sección transversal* del terreno en la estación O. Después trácese en el plano, como en la fig. 1, líneas *mn*, ó *hw*, en ángulo recto al eje del camino, y que pasen por las estacas donde se hizo estación. Sobre esta línea trácense las distancias horizontales *ad*, *ds*, *sv*, *ae*, *eg*, *gk*, marcándo as con un asterisco pequeño, como se hizo y se indicó con letras en la fig. 1 en la estación O.

Cuando se requiere mucha exactitud, estas distancias horizontales deben obtenerse por medidas hechas en la fig. 3; pero en general será suficiente aproximación, cuando las pendientes del terreno no exceden de 10°, suponer que son lo mismo que las distancias inclinadas medidas en el tereno. Ahora averíguese qué cota corresponde á cada uno de los puntos *c*, *y*, *t*, *l*, *n*, *i*, sobre el plano de comparación. Así: Mídase por la escala la dist vertical *cd*, fig. 3. Supongamos que sean 5 metros, ó en otras palabras, que *c* esté 5 metros *debajo* de la estaca O. Como la cota de O es 100 metros, la de *c* será 5 metros *menos*, ó 100—5=95 metros, la cual puede indicarse ligeramente con un lápiz en el plano, como en *d*, fig. 1. Ahora bien, con respecto al punto *y*, suponiendo que hemos encontrado para *sy* 11 metros, ó que *y* está á 11 metros *debajo* de la estaca O, su altura sobre el plano de comparación será 100—11=89; que marcaremos también con lápiz, como en *s*. Procédase de la misma manera con *t*. Luego pasando al lado izquierdo de la estaca encontramos

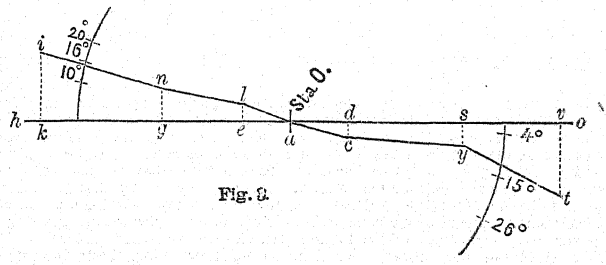

Fig. 3.

que *el*, por ejemplo, son 2 metros; pero como *l* está *sobre* el nivel de dicha estaca, su altura sobre el plano de comparación será, de consiguiente, 100+2=102 metros, como está indicado en *e* en el plano. Supongamos que *ng* sean 5 metros; entonces *n* estará á 100+5=105 metros sobre el plano de comparación, como se indica en *g*, y así en cada estación.

Cuando esto se haya hecho en varias estaciones, podremos trazar las curvas de

nivel de aquella parte á la mano así. Suponiendo que ellas han de representar equidistancias verticales de 3 metros. Principiando á trazar en el punto O, fig. 1 (cuya cota es de 100 metros sobre el plano de comparación), una curva de nivel de 103 metros de cota, vemos desde luego que la altura de 103 metros corresponde al punto *t*, situado á $^1/_3$ de la dist de *e* á *g*. Hágase una marca ligera con lápiz en *t*, y sígase á la próxima estación 1, donde vemos que la altura de 103 metros coincide con la misma estaca; márquese allí otro punto con lápiz y sígase á la estación 2. La cota de esta estaca es 101 metros; por lo tanto, la curva de nivel de 103 metros de cota está 2 metros más alta, ó en *i*, á $^2/_3$ partes de la distancia comprendida entre la estaca 2 y +104; márquese un punto con lápiz en *i*.

Sígase á la estación 3. Siendo la cota de este punto 104 metros, la curva de nivel de 103 metros de cota debe pasar por *y* ó á $^1/_3$ de la distancia de la estación 3 á +99; márquese un punto con lápiz en *y*. Finalmente, trácese á la mano una curva por *t*, S1, *i*, *y*, y quedará trazada la curva 103. Todas las otras se trazan de la misma manera, una por una. La cota de cada una de ellas debe anotarse en el mapa á distancias cortas, como en 103*c*, 106*c*, etc. O, en lugar de poner primero los puntos así marcados sobre el plano, para indicar las distancias inclinadas verdaderas, medidas en el terreno, podemos de una vez, y con menos trabajo, encontrar y fijar solamente las que representan los puntos *t*, S1, *i*, *y*, etc., de las curvas de nivel mismas. Así: Sea 104, por ejemplo, la cota de cualquier estaca, fig. 4; que la sección transversal *cs* haya sido dibujada como antes, y que necesitamos las distancias horizontales de la estaca á las curvas de nivel de 94, 97, 100 metros, etc., con cotas de 3 metros de equidistancias verticales.

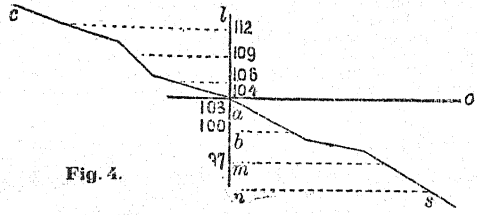

**Fig. 4.**

Tírese una línea vertical, *vl*, por la estaca y en ella márquense por la escala las cotas 94, 97, 100, etc. Esto se puede hacer fácilmente, puesto que tenemos la cota, dada 104 de la estaca. Por estos puntos trácense las líneas horizontales *a*, *b*, *m*, *n*, etc. á la línea de pendiente del terreno; entonces estas líneas horizontales, medidas por la escala, nos darán evidentemente las distancias requeridas.

Cuando el terreno es muy irregular ó quebrado transversalmente, las secciones transversales deben tomarse sobre el terreno á distancias unas de otras de menos de 30 metros. El trazado de las curvas de nivel se facilita mucho con el uso del papel cuadriculado de no menos de 2 milímetros por lado que hace también muy fácil el trazado de las secciones transversales.

Cuando el terreno es muy escarpado, se acostumbra sombrear el plano para representar las elevaciones.

Mientras más próximas queden en el dibujo las curvas de nivel, tanto más escarpado será, por supuesto, el terreno comprendido entre ellas; y la sombra debe ser relativamente más obscura en dicha porción del plano.

Pero en los planos de *trabajo* es mejor omitir la sombra.

En levantamientos de comarcas extensas se usa el tránsito de círculo ó arco graduado vertical *g*, pág. 301, para medir los ángulos de inclinación, en lugar del eclímetro ordinario.

En muchos casos, en los levantamientos para ferrocarriles, se reemplazan las curvas de nivel con simples notas como la siguiente:

| | | |
|---|---|---|
| Est 60 | $-3.1$ D | $+2.1$ Y |
| 61 | $+2.2$ D | $-1.3$ Y |
| 62 | $=1.$ D | $+4.2$ Y |
| 63 | — | — |

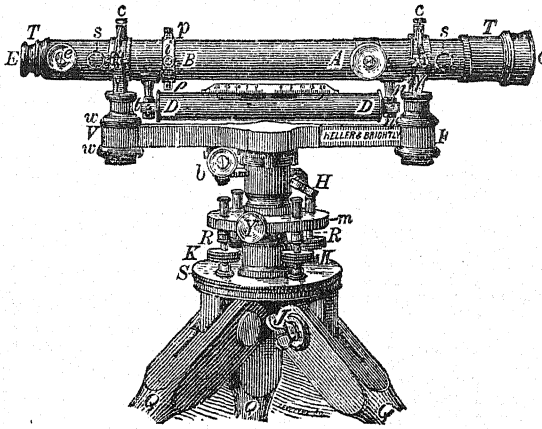
Lo que quiere decir que en la estación 60, la pendiente del terreno determinada aproximadamente á la vista ó con un nivel de mano, va en descenso hacia el lado derecho á razón de 3 metros en la dist de una cadena ó 30 metros, y hacia la

izquierda, sube como 2 metros por cadena. En la 61, sube 2 metros, en dos cadenas á la derecha, y baja 1 metro en 3 cadenas á la izquierda. En la 62, el terreno está á nivel hasta una cadena á la derecha, y asciende 4 metros en dos cadenas á la izquierda. En la 63, lo mismo que en la 62. En algunos puntos bastaría solamente agregar un croquis (de la sección transversal) semejante á la fig. 2 en lugar de los ángulos, y tomar los metros de ascenso ó descenso, para indicar las pendientes, determinadas á la simple vista ó con un nivel de mano. De este modo el resultado tendrá un pequeño error en cada estación; pero estos errores tan pequeños casi se compensan unos á otros, de manera que el resultado total puede considerarse suficientemente correcto para hacer los cálculos preliminares del costo de una vía. Cuando se colocan las estacas finales para guía de los trabajadores, entonces deben determinarse las pendientes con exactitud, para calcular el movimiento de tierra y hacer los pagos.

# EL NIVEL

Aunque los niveles de los diferentes fabricantes varían algo en sus detalles, las partes principales que los constituyen pueden comprenderse por medio de la figura siguiente. El anteojo TT descansa sobre dos soportes YY, llamados *ies*, de los cuales se puede levantar sacando las clavijas *ss*, que aseguran las dos *abrazaderas* semicirculares *cc*, y luego abriendo éstas. Las clavijas *ss* deben atarse á los soportes con una cuerdita para evitar que se pierdan.

El *tubo movible* que contiene el objetivo O, se desliza hacia adelante y hacia atrás por medio de un tornillo de cremallera, con la cabeza acordonada A. El del *ocular* E se mueve de la misma manera por medio del tornillo acordonado *e*. Casi todo nivel



tiene un tubo cilíndrico de bronce, llamado *pantalla*, que se corre sobre la parte del anteojo que contiene el objetivo, para evitar los reflejos del sol sobre aquél cuando éste está bajo. B es un anillo exterior que envuelve el anteojo y tiene 4 tornillos pequeños, dos de ellos, *pp*, están en las partes superior é inferior, mientras que los otros dos, de los cuales *i* es uno, se hallan en los lados del tubo y en ángulo recto á *pp*. Del lado interior de este anillo exterior y en el inferior del anteojo hay otro anillo, que tiene atravesadas dos hebras de tela de araña, llamadas generalmente *pelos transversales*. Son mucho más delgadas de lo que parecen, porque están aumentadas considerablemente por la lente. Estos pelos están en ángulo recto uno con otro; y al nivelar se mantiene uno vertical y el otro horizontal.

Algunas veces están expuestos á salirse de su posición, cuando se transporta el nivel al hombro de una parte á otra, ó cuando se coloca bruscamente la trípode en el suelo; pero como al nivelar se dirige la *intersección* de los pelos hacia la mira, este desarreglo no afecta la exactitud del trabajo. Sin embargo es mejor conservarlos próximamente verticales y horizontales por medio del nivel de aire DD.

Esto le facilita al nivelador ver si el que lleva la mira tiene ésta casi vertical, lo que es absolutamente esencial para una nivelación correcta.

Si se desea la perfecta verticalidad de la mira, como es necesario cuando se quieren colocar con mucha precisión estacas para el trabajo, esto se puede conseguir (*si el instrumento está perfectamente corregido y á nivel*) dirigiendo la vista á una plomada ú otro objeto vertical, y haciendo girar entonces el anteojo un poco en sus *ies* hasta que coincida el pelo con la línea vertical. Hecho esto, puede hacerse una marca ligera y continua, en el anteojo y el soporte, para evitar rectificaciones en lo sucesivo.

*Advertencia del Traductor.* — Así se sabe si la mira no está inclinada, hacia la derecha ó izquierda del observador, respecto á la verticalidad *en el plano perpendicular á la visual;* pero, la falta de verticalidad de la mira *en el plano mismo de la visual*, porque su extremo superior esté inclinado hacia el observador ó en sentido contrario, no se puede apreciar bien desde el anteojo, ni por el anteojo; es necesario que el peón portamira tenga una plomada que lo guíe al plantar la mira. Para precaverse de los descuidos del portamira, en este sentido, es lo más práctico ordenarle un pequeño movimiento oscilatorio de la mira en el plano de la visual y tomar *la menor lectura que marque el pelo horizontal* (ó mejor la intersección de los pelos) al aparecer éste, moviéndose de arriba hacia abajo y viceversa sobre las divisiones de la mira, á causa del movimiento oscilatorio de ésta.

Los señores Heller Brightly dotan los niveles que fabrican de un pequeño resalto ó parte saliente en las *ies*, y otro correspondiente en el anteojo, cuyo contacto asegura la verticalidad del pelo. Si se rompen los pelos por un accidente, pueden reponerse como se explica más adelante.

Los pequeños agujeros que se encuentran alrededor de los cuatro tornillos *ip* aludidos, son para introducir el extremo de una pequeña clavija de acero, con la cual se les hace girar. Si se afloja primero el tornillo superior *p* y se aprieta el más bajo, el anillo interior descenderá y con él el pelo horizontal; pero al mirar por el anteojo *parece* que han subido. Aflojando primero el tornillo inferior y apretando el superior, el pelo horizontal sube realmente; pero visto por el anteojo, baja aparentemente. Resulta esto, porque las lentes del ocular E invierten la posición aparente de los objetos en el *interior* del anteojo, cuyo efecto se evita, para los objetos *exteriores*, por medio del objetivo O. Debe tenerse presente esta circunstancia a, arreglar los pelos, porque cuando un pelo parece intersectar demasiado alto, debe aún elevarse más, y si el pelo vertical parece demasiado á la derecha ó á la izquierda para corregirlo debe moverse más en el mismo sentido.

Esta observación no se aplica á los anteojos que invierten los objetos.

No hay peligro de que se dañen los pelos con estos movimientos, porque los 4 tornillos no actúan sino sobre el anillo, y no llegan á tocar los pelos mismos.

Debajo del anteojo se halla el *nivel de aire* DD. Un extremo de este nivel puede subirse y bajarse ligeramente por medio de las dos tuercas de tornillo *nn*, una de las cuales debe aflojarse antes de apretar la otra.

En la parte superior del tubo hay unas rayas para indicar cuándo la burbuja está en el centro. A menudo se hacen las rayas en una tira de bronce colocada sobre el tubo, como se observa en la figura. De estas rayas hay varias, para abarcar la burbuja en sus dilataciones y contracciones ocasionadas por los cambios de temperatura. En la otra extremidad del nivel hay dos tornillos pequeños colocados horizontalmente en los lados opuestos. La cabeza circular de uno de esos tornillos se ve cerca de *t*. Por medio de ellos puede moverse el extremo mencionado del nivel, un poco horizontalmente hacia la derecha ó hacia la izquierda. Debajo del nivel de aire está la barra VF, que en una de sus puntas, V, tiene dos tuercas grandes *w*, *w*, que obran sobre un tornillo fuerte interior, que forma una prolongación del soporte Y. Los agujeros de estas tuercas son más grandes porque necesitan de una palanca más grande para darles vuelta.

Si se afloja la tuerca inferior y se aprieta la superior, el soporte Y sube y la extremidad correspondiente del anteojo se aleja de la barra y viceversa. Algunos fabricantes colocan tornillos y tuercas semejantes debajo de ambos soportes, mientras que otros no ponen tuercas sino una cabeza grande cilíndrica acordonada, que se le da vuelta con los dedos. Ésta está expuesta sin embargo á alteraciones accidentales que deben evitarse.

Cuando la porción del instrumento de *m* hacia arriba se coloca sobre *m*, y se as

gura con el tornillo Y„puede hacerse girar horizontalmente aflojando el **tornillo de presión** H; ó apretando éste, impedir todo movimiento.

Sucede frecuentemente que después que el anteojo se ha dirigido muy cerca de un objeto, y está fijo con el tornillo H, deseamos hacer coincidir los pelos transversales con el objeto más exactamente de lo que se puede hacer, dándole vuelta al instrumento *con la mano;* y en este caso usamos el **tornillo tangencial** *b*, por cuyo medio podemos dar al instrumento un movimiento pequeño, pero regular, después de fijo. Para más detalles sobre los tornillos de presión y tangenciales, véase « Tránsito ».

**Las placas paralelas** *m* y S se mueven por medio de los cuatro **tornillos de nivelar**, de los cuales se ven tres, KK, en la figura.

Estos tornillos trabajan en encajes R, los que al igual de los tornillos se prolongan hasta la placa superior.

Cuando se instala el instrumento en el suelo para nivelar, es conveniente colocarlo de manera que la placa paralela inferior S esté casi horizontal á la simple vista, para evitar en cuanto sea posible trabajar mucho con los tornillos de nivelación KK, al poner horizontal la placa superior *m*. La placa inferior S y las piezas de bronce en conexión con ella, se llaman **cabeza de la trípode**; y junto con las tres patas de madera, QQQ, constituyen la trípode. En la figura se ven las tuercas de aletas J que fijan las patas á la cabeza de la trípode.

Debajo del centro de ésta debe haber siempre una argolla pequeña para colgar la plomada. Esto no se necesita en una nivelación ordinaria, pero sí al colocar estacas de centro y otros trabajos de precisión.

## Corrección del nivel.

Esta es una operación muy sencilla, pero que requiere un poco de paciencia. Téngase cuidado de *no forzar* ninguno de los tornillos. Las grandes tuercas *ww* de las Y necesitan algunas veces de un poco de fuerza para *principiar á moverlas;* pero esta fuerza debe aplicarse por presión paulatina y no por golpes. Antes de principiar las correcciones, hágase con el objetivo lo que se dijo al empezar el párrafo titulado « Corrección de un tránsito común ».

Un nivel necesita tres correcciones *que deben hacerse en el orden siguiente :*

**Primero, la de los pelos transversales.** Cerciorarse si su cruzamiento continúa intersectando siempre el mismo punto de un objeto distante durante una vuelta completa del anteojo en sus apoyos *. Esto se llama corregir el **eje de colimación**, ó algunas veces la *línea visual;* pero no es estrictamente la línea visual hasta no *concluir* todas las correcciones, pues hasta entonces la línea ó eje de colimación no servirá para dirigir visuales de nivelación.

**Si se rompen los pelos transversales**, véase la pág. 307.

**Segundo, la del nivel de aire** DD. Hacer que éste sea paralelo al eje ó línea de colimación ya corregido, de manera que estando la burbuja en el centro de su tubo y, por consiguiente, indicando que está horizontal, sepamos que la visual dirigida por el anteojo es horizontal. Para reponer **un nivel de aire roto**, véase pág. 308.

**Tercero, la de los apoyos** YY que sostienen el anteojo y el tubo del nivel de aire. Hacer que el eje del nivel y la visual dirigida sean perpendiculares al eje vertical del instrumento, para que de esta manera *permanezca* horizontal cuando se dirija el anteojo hacia objetos situados en diferentes direcciones, como cuando se dirigen visuales atrás y adelante.

**Para hacer la primera corrección**, es decir, la de los pelos transversales, póngase la trípode *firmemente* en el suelo. En esta corrección no es necesario poner el instrumento á nivel. Abranse las abrazaderas de los apoyos; sáquese el ocular E, hasta que los pelos transversales se vean *perfectamente claros;* diríjase la visual hacia un punto claro de algún objeto distante ó, mejor todavía, hacia una línea recta vertical ó no. Por medio de la cabeza acordonada A, muévase el objetivo O hasta que se vea *claro* el objeto, **y sin paralaje**; esto es, sin que se note un movimiento aparente alrededor de los pelos, al mover el ojo un poco hacia arriba ó hacia abajo, ó lateralmente. Para conseguir esto, el objetivo solo es el que debe moverse cuando se quiere graduar el instrumento para diferentes distancias; el ocular no se mueve después de fijo y de que se ven los pelos con claridad. La falta de atención en la paraluje es origen de frecuentes errores en la nivelación. Fíjese

---

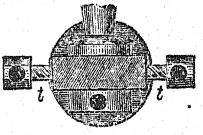
* *N. del T.* — Es decir, que el punto de intersección de los pelos se halle en el eje óptico del anteojo, lo que se verifica si coincide siempre con el mismo punto de un objeto lejano durante una vuelta completa del anteojo alrededor de sus YY.

el anteojo con el tornillo de presión, y con el tornillo tangencial hágase coincidir *exactamente* á cualquiera de los pelos con el objeto. Luego, con suavidad y sin trepidación, désele media vuelta al anteojo en los apoyos. Hecho esto, si el pelo todavía coincide exactamente con el objeto, el instrumento estará correcto y procedemos á probar el otro pelo. Pero si no coincide, por medio de los 4 tornillos *i p*, muévase el retículo que contiene los pelos, hasta rectificar lo más que se pueda á la simple vista, *la mitad* del error solamente; recordando que el retículo debe moverse en dirección opuesta á la en que parece estar, á menos que el anteojo invierta los objetos.

Entonces, désele vuelta al anteojo á la inversa hasta llevarlo á su posición anterior y hágase coincidir otra vez el pelo con el objeto por medio del tornillo tangencial. Ahora hágase girar el anteojo como antes, y se encontrará el pelo casi en la posición deseada, aunque probablemente no con toda exactitud, porque es muy difícil estimar á la vista con precisión la mitad del error.

Por lo tanto debe hacerse otra pequeña alteración al retículo y puede que sea necesario repetir la operación varias veces antes de que se llegue á la perfecta corrección. Por último, trátese el otro pelo de la misma manera. Cuando ambos pelos estén corregidos, su intersección marcará con exactitud el mismo punto durante una vuelta *entera* del anteojo en los apoyos. Esto debe comprobarse antes que demos por terminada la corrección, porque algunas veces la del segundo pelo desarregla el primero; especialmente si, al principiar, ambos tenían un error notable

**Para hacer la segunda corrección** ó para poner el tubo de burbujas paralelo al eje del anteojo se hacen dos correcciones separadas, una vertical y otra horizontal. La primera de éstas se efectúa por medio de las dos tuercas *nn*. que están sobre el tornillo vertical en un extremo del nivel; y la segunda con los dos tornillos horizontales de la otra punta del mismo nivel. Viendo el tubo del nivel de punta en *t*, en esta figura inmediata, sus dos tornillos de corrección *tt* se ven como en la figura. La tuerca más grande de *abajo* nada tiene que hacer con las correcciones, sólo mantiene la punta del tubo en su puesto. Para hacer



las correcciones verticales del nivel de aire por medio de las dos tuercas *nn*, póngase el anteojo sobre dos de los tornillos diagonales KK de nivelación y fíjese. Abranse las abrazaderas de las YY, y por medio de los tornillos de nivelación llévese la burbuja al centro del tubo. Levántese suavemente el anteojo é inviértase su posición, poniendo el objetivo donde estaba el ocular y colóquese de nuevo en sus apoyos así invertido. Hecho esto, si la burbuja permanece todavía en el centro, estará correcto; pero si se mueve hacia uno de los extremos, dicho extremo estará demasiado alto y debe bajarse éste ó levantarse la otra punta. Primero, corríjase la *mitad* del error por medio de los tornillos de nivelación KK, y la otra mitad con las tuercas ó tornillos *nn* del tubo de la burbuja. Para *elevar* la punta *n* aflójese primero la tuerca superior y apriétese la inferior, y para efectuar esto, désele vuelta á cada tuerca, de manera que el lado *más próximo* de cada uno se mueva hacia la *derecha*. Para *bajarlo*, aflójese primero la tuerca inferior y apriétese la superior, moviendo el lado *más próximo* de ellas hacia *la izquierda*. Habiéndose llevado la burbuja de este modo otra vez al centro, levántese otra vez el anteojo de las YY, é inviértase y colóquese de nuevo en su lugar. La burbuja se quedará ahora más cerca del centro que antes; pero probablemente necesitará aún otros tanteos. Si fuese así, corríjase la *mitad* del error restante por medio de los tornillos de nivelación, y la otra mitad por medio de las tuercas del tubo como antes, y continúese repitiendo así la operación hasta que la burbuja permanezca en el centro en ambas posiciones. Con respecto á otros métodos, véase « Para corregir el tubo largo del nivel de aire », pág. 306. La corrección horizontal del nivel de aire es para ver si su eje está en el mismo plano que el eje del anteojo, como lo está generalmente en los instrumentos nuevos. El desarreglo en este sentido no se produce fácilmente sino por golpes fuertes. Colóquese el nivel de aire debajo del anteojo lo más que se pueda en la dirección de éste, ó sobre el eje de la barra VF. Llévese el anteojo sobre dos de los tornillos de nivelación KK.

fíjesele allí y llévese la burbuja á su centro por medio de dichos tornillos; hágase girar alrededor de su eje al anteojo en sus *Yes* como seis milímetros, llevando el nivel de burbuja fuera del eje de la barra, primero hacia un lado y después hacia el otro. Si la burbuja permanece en el centro durante la operación, no hay corrección que hacer. Si dicha burbuja, durante el movimiento de vaivén ú oscilatorio comunicádole hacia los lados opuestos al eje, corre hacia los extremos *opuestos* del tubo, muévase entonces la punta *t* por medio de los tornillos horizontales *tt* hasta que la burbuja se quede en su centro durante el desalojamiento del nivel hacia ambos lados del eje mencionado. Si la burbuja corre hacia la misma punta del tubo *en ambos lados*, es porque el tubo no es verdaderamente cilíndrico, sino ligeramente cónico *, de modo que si se hace girar el anteojo en sus soportes, la burbuja se saldrá de su centro, aunque la corrección horizontal esté bien hecha. En los tubos de esta especie se conoce, que la corrección horizontal está perfecta, en que la burbuja recorre desde el centro la misma cantidad cuando se desvía dicho tubo la misma dist hacia ambos lados. Hecha la corrección horizontal, vuélvase atrás el anteojo en sus Yes hasta que el nivel de burbuja esté directamente sobre el centro de la barra. Repítase la corrección *vertical*, pág. 321, que puede haberse desarreglado mientras se hacía la horizontal. Continúese hasta que ambas correcciones resulten bien hechas al mismo tiempo.

**Tercera corrección ó corrección de la altura de las Yes,** hasta hacer que la línea de colimación sea paralela á la barra VF ó perpendicular al eje vertical del instrumento. Después de haber hecho las otras correcciones, asegúrense las abrazaderas de las Yes. Póngase el instrumento casi horizontal por medio de los cuatro tornillos K. Colóquese el anteojo sobre dos de los tornillos diagonales de nivelar y déjesele en dicha posición sin trancarlo, luego llévese la burbuja al centro del tubo por medio de los dos tornillos de nivelar. Désele media vuelta á la parte superior del instrumento, de manera que el anteojo quede de nuevo sobre los mismos tornillos; pero con el ocular donde estaba el objetivo.

Hecho esto, si la burbuja se sale del centro, hágasele retroceder la *mitad* por medio de las tuercas grandes *w, w*, y la otra mitad por medio de los tornillos K. Recuérdese que para elevar ó hacer subir el soporte Y y el extremo del nivel de aire sobre *w w*, la *w* inferior debe aflojarse y la superior apretarse y viceversa. Ahora colóquese el anteojo sobre los otros dos tornillos diagonales y repítase toda la operación con ellos. Habiéndola concluído, hágase la prueba otra vez con el primer par de tornillos, y sígase así hasta que la burbuja se quede en el centro de su tubo, en cualquiera posición del anteojo. Puede nivelarse correctamente aun cuando no se haya hecho ninguna de las correcciones mencionadas, con tal que *cada visual ó golpe de nivel hacia adelante se haga á la misma dist del instrumento que la visual ó golpe de nivel hacia atrás;* pero un buen nivelador tendrá siempre su instrumento corregido y lo rectificará por lo menos una vez por día, cuando esté trabajando †.

Mucho depende la exactitud de una nivelación del que carga la mira. Un hombre que sea descuidado en mantener la mira vertical, ó que no lea las graduaciones con exactitud, debe despedirse sin consideración alguna **.

---

* Este defecto puede solamente remediarse sacando el tubo y colocando otro de forma correcta, lo cual será mejor hecho por un fabricante de instrumentos; pero, á pesar de todo, puede efectuarse un trabajo perfecto de la manera siguiente: Háganse todas las correcciones tan aproximadamente exactas como se pueda; póngase á nivel el instrumento. Girando el anteojo en sus apoyos (YY), hágase coincidir el pelo vertical con una plomada ú otra línea vertical y practíquese con un cortaplumas una raya continua en el anillo más próximo al objetivo y prolónguese esta marca hasta el apoyo adyacente. Levántese el anteojo de las Y é inviértase de modo que el objetivo ocupe el lugar del ocular; colóquese otra vez en sus apoyos; póngase nuevamente vertical el pelo del anteojo, y en el otro apoyo hágase una raya que coincida con lo que se hizo en el anillo inmediato al objetivo; luego al nivelar ó corregir, véase siempre si la raya del anillo coincide con la del apoyo adyacente cuando el nivel de aire está debajo del anteojo.

† *N. del T.* — Siempre será conveniente corregir el instrumento lo más á menudo posible; pero como en nivelaciones de carácter urgente las tres correcciones del nivel quitarían mucho tiempo al hacerlas diariamente, creemos muy suficiente en estos casos limitarse á efectuar diariamente sólo la primera de las dos partes de que consta la *segunda corrección*.

** *N. del T.* — Esto será en el caso en que se usen *miras de corredera* que ofrecen el inconveniente de que no puede leerlas el observador sin trasladarse de la estación al punto de mira ó proveerse de un peón portamira que haga la lectura; esto se usa poco,

Los tornillos de nivelar se ponen muy apretados con el polvo y es difícil darles vueltas. Límpieselos con agua y un cepillo de dientes. No se use aceite en los instrumentos de campo.

**Forma de las minutas de nivelación.** Cuando la dist es corta y no se requieran dos juegos de libretas, la forma siguiente de minuta es tan buena quizá como cualquiera otra.

| N.° de la Estación. | Visual á la espalda. | Visual al frente. | Difer. | Cotas. | Pendiente. | Banqueo. | Terraplén. |
|---|---|---|---|---|---|---|---|

Pero en las Obras públicas no se usan sino las primeras cinco columnas. Después de haberse determinado la pendiente por medio del perfil trazado, se anotarán los resultados en otra libreta que tiene solamente la primera y las cuatro columnas últimas. En ambos casos la página del lado derecho se deja para las observaciones. El autor cree que sería mejor considerar el término «Estación» tanto en las operaciones que se hagan con el nivel como en las que se efectúen con el tránsito aplicado á la dist total comprendida entre dos estacas consecutivas; y que su número se escriba sobre la última estaca. Así, con el tránsito, la estación 6 quiere decir la dist de la estaca 5 á la estaca 6, y que tiene tal ó cual dirección y que su extensión es tal ó cual. Y con el nivel, la estación 6 indica la dist de la estaca 5 á la estaca 6, habiéndose hecho la visual á la espalda en la estaca 5 y la visual adelante en la estaca 6, y que la cota, la pendiente y el banqueo ó terraplén se refieran á la estaca 6. El punto de partida de un levantamiento se llamará 0 (cero), ya sea una estaca ú otra cosa cualquiera **.

| Estación. | Visual al frente (aditiva). | Altura del ojo. | Visuales á la espalda (sustractivas). | Cotas. |
|---|---|---|---|---|
| 1 | 1.50 | 101.50 | | 100 |
| 2 | | | 2.25 | 99.25 |
| 3 | | | 2.50 | 99.00 |
| 4 | 3.20 | 101.20 | 3.50 | 98.00 |
| 5 | | | 4.10 | |

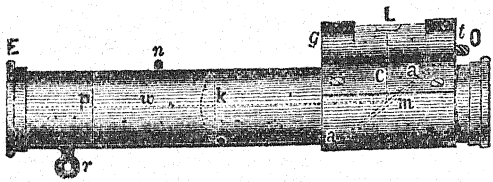
(*Explicación.* En el punto de partida, que llamaremos estación 1, cuya cota suponemos ser 100, tomaremos la primera lectura de mira, por ejemplo 1.50, que como visual al frente es aditiva. Sumada esta altura de mira con la cota 100 de la estación 1, obtendremos 101.50=la altura del eje óptico del instrumento ú ojo del observador. Trasladada la mira sucesivamente á las estaciones 2, 3, 4, etc., tomaremos nuevas lecturas 2.25, 2.50, 3.50, etc., *sin cambiar el instrumento*, las que restadas (como sustractivas que son) de la altura de ojo dicha, darán las cotas 99.25, 99.00, 98.00, etc., de aquellos puntos. Al cambiar el instrumento para continuar la nivelación, dejaremos la mira en la última estación 4, cuya cota es 98; y se toma sobre ella, después de cambiar el instrumento, una nueva lectura de mira que viene á ser *visual al frente* en la nueva posición del instrumento. Supongámosla igual á 3.20; como es aditiva, la sumaremos con la cota 98 de la estación 4, donde se dejó la mira, obtendremos 101.20, altura del ojo en la nueva posición del instrumento. Mudando la mira á otras estaciones siguientes, verbigracia 5, sin cambiar el instrumento leeremos en ella, por ejemplo 4.10, que restado de 101.20 dará 97.10, cota de la estación 5, y así sucesivamente.)

---

aunque puede ser de gran utilidad cuando se hacen observaciones á grandes dist. Es más expedito emplear la *mira*, de 4 m 20 á 5 m de largo, dividida en decímetros, centímetros y á veces en milímetros, la cual nos excusamos de describir por ser muy conocida. Para mantener su verticalidad puede agregársele una plomada convenientemente dispuesta; y para evitar hundimientos en terrenos blandos, colocar dicha mira sobre un *galapaguito* de hierro, con las tres puntas ó esquinas dobladas igualmente para apoyarlo en el suelo.

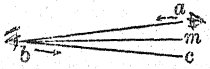
** *N. del T.* — Recomendamos esta minuta que nos parece muy práctica.

## NIVEL DE MANO



Este pequeño y muy útil instrumento, tal como lo ha dispuesto el profesor Locke, de Cincinnati, es más ó menos de 12½ á 15 centímetros de largo. Sosteniéndolo simplemente en una mano y viendo por él en cualquiera dirección, podemos determinar desde luego, muy aproximadamente, los objetos que se hallan al mismo nivel del ojo. E, es el ocular y O el objetivo; L es un nivelito colocado dentro de una especie de caja de bronce, *tg*, cuyo fondo está abierto, y hay debajo de él, en la parte superior del tubo principal EO, una abertura correspondiente. Inmediato al fondo del nivel L hay un hilo colocado transversalmente á dicha abertura y fijo sobre una placa pequeña, la que puede empujarse un poco hacia atrás para ajustar el alambre, apretando el tornillo *t*, ó empujarse hacia adelante por medio de un pequeño resorte que hay entre la caja cerca de *g*, cuando se afloja el tornillo *t*. En *m* hay un espejito semicircular *aa*, azogado en su dorso *m*, inclinado á 45º y ocupa la mitad del ancho del tubo EO. A través de las aberturas arriba mencionadas se reflejan las imágenes del hilo transversal y de la burbuja del nivel sobre la cara no azogada *aa* del espejo, y de aquí hacia el ojo, como se indica por las líneas de puntos *c* y *w*, y cuando el instrumento está arreglado y mantenido horizontalmente, el hilo parece estar en el centro de la burbuja. En K se halla la mitad de una lente plano-convexa, en el extremo interior de un tubo corto *pk*, que puede moverse hacia adelante ó hacia atrás por medio de una clavija *n* que sobresale a través de una pequeña ranura hecha en el tubo principal. Por este medio se llega á ver clara la imagen del hilo transversal; y la semilente debe moverse hasta que, al ver el objeto, el hilo no manifieste paralaje, sino que aparezca fijo sobre el objeto, cuando se mueva el ojo ligeramente hacia arriba ó hacia abajo. En cada punta del tubo EO hay una pieza circular de vidrio plano para evitar que entre el polvo.

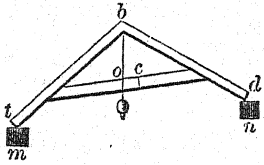
**Corrección del nivel de mano.** Fíjense primeramente dos puntos exactamente á nivel como de 20 á 100 metros de distancia uno del otro. Hecho esto, colóquese el instrumento en uno de ellos y diríjase la visual al otro. Si entonces el hilo no parece estar exactamente en el centro de la burbuja, muévasele ligeramente hacia adelante ó hacia atrás, según el caso, por medio del tornillo *t*, hasta que lo



parezca. Los dos puntos á nivel pueden fijarse por medio del nivel de mano mismo, aunque no esté corregido; así: Primero, por medio de la clavija *n* arréglese la semilente *k* hasta que se vea claro el hilo y sin paralaje. Luego, teniendo el nivel fijo en cualquier objeto *a* de manera que el hilo parezca intersectar el centro de la burbuja, obsérvese donde intersecta á cualquier otro objeto conveniente *b*. Luego váyase á *b* y diríjase desde allá del mismo modo, visual atrás hacia *a*. Si el instrumento está correcto, el hilo intersectará á *a;* pero si no, á cualquier otro punto *c* situado más abajo ó más arriba. En uno ú otro caso hágase una marca *m*, en medio de *c* y *a*, y entonces *b* y *m* serán los puntos á nivel requeridos. Hechas desde luego estas correcciones con cuidado, permanecerá el instrumento en buen estado por algunos años. Generalmente el instrumento está provisto de un pequeño anillo ó ganchito *r* para cargarlo colgando del cuello. No es propio para un trabajo de mucha exactitud, pero es admirable para explorar un camino. La altura de un cerro desnudo ó sin vegetación puede hallarse principiando en el pie, y dirigiendo el nivel á cualquier objeto que el hilo intersecte, como una piedrita, etc., luego avanzando nos colocamos sobre este objeto y se fija el hilo sobre otro que se halle más allá, y así hasta llegar á la cima. En cada observación es claro que subimos una altura igual á la de

nuestro ojo, por ejemplo $1^m75$, ó lo que fuere. Ya sea subiendo ó bajando, si el cerro está cubierto de paja, arbustos, etc., hágase uso de una mira de corredera para tomar las visuales adelante, y la altura constante del ojo puede considerarse como la visual atrás en cada estación. Puede proveerse el instrumento de un empalme para atornillarlo al extremo de una caña ó de un bastón largo armado de una articulación esférica, ó de rodillo cuando se necesita más exactitud.

**Corrección del nivel de albañil ó de perpendículo** *tbd.* Colóquesele sobre dos soportes *m* y *n*, y márquense en *o* donde toca la plomada, luego inviértase,



colocando el extremo *t* donde está *n* y *d* sobre *m*; márquese la dirección de la plomada y hágase una marca permanente en el medio de *o*, y *c*. Cuando el hilo de la plomada coincide con esta marca, los dos extremos *t* y *d* están á nivel.

**Corrección de un nivel de pendiente ó eclímetro.** Generalmente el nivel de aire está adherido á una barra movible por medio de un tornillo cerca de cada extremo, y la cabeza de uno de los tornillos entra en una cavidad practicada en la barra que permite al tornillo un ligero movimiento vertical cuando está flojo, y con él á la extremidad del tubo. Por tanto, para arreglar la burbuja se afloja primero este tornillo y se le mueve un poco hacia arriba ó hacia abajo, según se requiere, y entonces se vuelve á apretar.

## NIVELACIÓN POR MEDIO DEL BARÓMETRO

**1.** Muchas circunstancias se reunen para hacer que se desconfíe de los resultados de esta especie de nivelación cuando se requiere gran exactitud. El hecho de que tales circunstancias influyen desfavorablemente, está comprobado de manera concluyente por las observaciones hechas por el capitán T. J. Cram, de la U. S. Coat Survey. Véase el informe de la U. S. Coat Survey del año de 1854. Es difícil apreciar con un aneroide (clase de barómetro que generalmente se emplea en los trabajos de ingeniería) difs de nivel de 0.50 á 1½ ó 2 metros. La humedad ó sequedad del aire afectan los resultados. De igual modo, los vientos, la proximidad de las montañas y el flujo y reflujo atmosféricos, son causas de fluctuaciones irregulares é incesantes en el barómetro. Un barómetro colgado en un cuarto sin moverlo, varía á menudo 2½ milímetros en pocas horas, y esto representa una dif de nivel próximamente igual á 30 metros. Es imposible idear una fórmula que comprenda todas estas causas de error. Las variaciones que dependen de la temperatura, de la latitud, etc., se han tomado en cuenta hasta cierto grado de exactitud, de manera que, con instrumentos *muy delicados*, un observador hábil puede medir la dif de nivel entre dos puntos cercanos, como la base y el extremo de una torre, con una aproximación de 50 cents á un metro. Pero si transcurre un intervalo de tiempo corto, como de algunas horas, entre las dos observaciones, pueden ocurrir tales cambios en la condición de la atmósfera, que puede resultar de las observaciones la punta superior de la torre más baja que su base, ó por lo menos una incertidumbre de tres ó seis metros, y esto puede ocurrir sin cambios perceptibles en la atmósfera. Cada vez que sea posible, debe situarse una persona en cada estación para observar en ambos puntos al mismo tiempo. Las observaciones hechas por una sola persona, en puntos á muchos kilómetros de distancia, y en diferentes estados de la atmósfera, son de poco valor. El término medio de muchas observaciones hechas en varios días, semanas ó meses, practicadas cuando está el aire sin aparentes perturbaciones, darán aproximaciones tolerables. En los trópicos, la diferencia de presión atmosférica es mucho menor que en otras regiones, variando rara vez y á lo sumo 12 milímetros en cualquier lugar. En estas regiones este método es más regular y por tanto menos susceptible de producir errores. Sin embargo, el barómetro, especialmente si es un aneroide, puede serle muy útil al ingeniero civil en casos donde no se requiere una gran exactitud. Cami-

nando á la ligera de un punto á otro, y repitiendo las operaciones, puede juzgarse cuál de dos cimas de cerros es la más elevada. Un observador cuidadoso, yendo algunos kilómetros adelante de una partida de ingenieros que practiquen un estudio, puede disminuirles mucho el trabajo, especialmente en los terrenos quebrados, escogiendo con anticipación la zona que deben seguir. Las referencias hechas de que se han efectuado nivelaciones de montañas elevadas por diferentes observadores con diferentes aneroides, y han concordado hasta algunos centímetros de aproximación, y de que se ha determinado la pendiente exacta de una vía férrea haciendo lecturas de barómetro dentro de un coche, no es creíble sino por personas ignorantes de la materia. Estos resultados se obtienen solamente por casualidad.

Si es posible, las observaciones en diferentes lugares deben hacerse á la misma hora del día para disminuir los efectos de los flujos y reflujos atmosféricos diarios; y en casos importantes, debe tomarse un memorándum del año, mes, día y hora, lo mismo que del estado del tiempo, dirección del viento, latitud del lugar, etc.

**Los efectos de la latitud** no están incluídos en ninguna de nuestras fórmulas. Si se necesitan pueden hallarse en la Regla 2, pág. 328. Deben hacerse algunas otras correcciones cuando se desea una exactitud grande; pero éstas requieren tablas extensas.

Al hacer exploraciones rápidas para un ferrocarril puede prescindirse de estos detalles, porque no se espera alcanzar tanta exactitud, sino que, por el contrario, á menudo ocurrirán errores de 25 centímetros á 3, ó más metros en una altura de 30 ó más metros.

**Como término medio aproximado** podemos suponer que el barómetro desciende 2½ milímetros por cada 27 metros de elevación sobre el nivel del mar hasta la altura de 300 metros; pero es el hecho que la proporción en que desciende disminuye continuamente á medida que se sube, de tal manera que á la altura de 1,609 metros el barómetro baja 2½ milímetros por cada 62m más ó menos. La tabla 2 indica la proporción verdadera.

## Determinación de la diferencia de altura entre dos puntos *.

*Regla* 1.ª Tómense las lecturas del barómetro y del termómetro (Fahrenheit) **en la sombra** en ambas estaciones, súmense las dos lecturas del barómetro y divídase la suma por 2 para obtener el término medio que llamamos *b*. Hágase lo mismo con las dos lecturas del termómetro y llámese *t* el término medio. Réstese la lectura menor del barómetro de la mayor y llámese la dif *d*, luego multiplíquese entre sí esta dif *d*; el número de la próxima tabla n.º 1 opuesto á *t* y el número constante 30. Divídase el producto por *b*, es decir:

$$\text{Altura en pies} = \frac{\text{Dif } (d) \text{ del barómetro} \times \text{Número tabular opuesto al término medio } (t) \text{ del termómetro} \times \text{Número constante } 30}{\text{Término medio } (b) \text{ del barómetro.}}$$

**Ej.**: Lectura del barómetro en la estación baja 26.64 pulgs; y en la estación alta 20.82. Del termómetro en la estación baja 70°, en la alta 40°.

¿Cuál es la diferencia de la altura entre las dos estaciones?

| | | | |
|---|---|---|---|
| Barómetro, | 26.64 | Termómetro, | 70° |
| — | 20.82 | — | 40° |
| | 2)47.46 | | 2)110° |
| | 23.73 = término medio del barómetro ó *b*. | | 55° = término medio del termómetro = *t*. |

El número tabular opuesto á 55° es 917.2.

Ahora, 26.64 — 20.82 = 5.82, diferencia de baróm; ó *d*. Se tiene entonces:

$$\text{Altura en pies} = \frac{5.82 \times 917.2 \times 30}{23.73 \text{ (ó } b)} = \frac{160143.12}{23.73} = \text{pies } 6{,}748.5$$

Cuando se quiera más exactitud hágase la corrección por medio de la tabla que sigue después, titulada **corrección por latitud.**

**El tornillo que está en la parte posterior** de los aneroides sirve para corregir el índice por medio de un barómetro normal. Después de haber hecho esto,

---

* *N. del T.* — Después de ésta damos las fórmulas y tablas en sistema métrico.

no se las debe tocar más. En algunos instrumentos mandados á hacer especialmente con este objeto, este tornillo puede emplearse también para volver á su lugar el índice, después de hacer subido á una elevación tan grande, que el índice haya llegado al límite extremo de la graduación. Después de haberlo vuelto á su lugar, las indicaciones que de nuevo dé para mayores elevaciones deben agregarse á las obtenidas antes de restituirlo á su puesto.

**TABLA 1.ª para la Regla 1.ª**

| Término medio del termómetro | Número. | Término medio del termómetro | Número. | Término medio del termómetro | Número. | Término medio del termómetro | Número. |
|---|---|---|---|---|---|---|---|
| 0° | 801.1 | 30° | 864.4 | 60° | 927.7 | 90° | 991.0 |
| 1 | 803.2 | 31 | 866.5 | 61 | 929.8 | 91 | 993.1 |
| 2 | 805.3 | 32 | 868.6 | 62 | 931.9 | 92 | 995.2 |
| 3 | 807.4 | 33 | 870.7 | 63 | 934.0 | 93 | 997.3 |
| 4 | 809.5 | 34 | 872.8 | 64 | 936.1 | 94 | 999.4 |
| 5 | 811.7 | 35 | 874.9 | 65 | 938.2 | 95 | 1001.6 |
| 6 | 813.8 | 36 | 877 0 | 66 | 940.3 | 96 | 1003.7 |
| 7 | 815.9 | 37 | 879.2 | 67 | 942.4 | 97 | 1005.8 |
| 8 | 818.0 | 38 | 881 3 | 68 | 944.5 | 98 | 1007.9 |

(*Advertencia del T.* — La fórmula análoga á la usada en la Regla 1.ª, y que debe emplearse cuando se usen las medidas barométricas en milímetros y las temperaturas en grados centígrados, es la siguiente:

$$\text{Altura en metros} = \frac{\text{diferencia } (d) \text{ del barom en milímetros} \times \text{número opuesto á la media temperatura en grados C} \times \text{número constante } 9.1437}{\text{media } (b) \text{ barométrica en milímetros.}}$$

Para buscar el número opuesto á la temperatura *en centígrados* se usará la tabla siguiente 1*a*.)

**TABLA 1ª para la advertencia del traductor á la Regla 1.ª**

| Media del termómetro. | Número. | Media del termómetro. | Número. | Media del termómetro. | Número. |
|---|---|---|---|---|---|
| — 16 | 807.8 | 5 | 887.5 | 26 | 967.3 |
| — 15 | 811.6 | 6 | 891.3 | 27 | 971.1 |
| — 14 | 815.4 | 7 | 895.1 | 28 | 974.8 |

| — 11 | 826.8 | 10 | 906.6 | 31 | 986.4 |
| — 10 | 830.6 | 11 | 910.4 | 32 | 990.2 |
| — 9 | 834.5 | 12 | 914.2 | 33 | 993.9 |
| — 8 | 838.3 | 13 | 917.9 | 34 | 997.7 |
| — 7 | 842.0 | 14 | 921.7 | 35 | 1001.6 |
| — 6 | 845.8 | 15 | 925.6 | 36 | 1005.4 |
| — 5 | 849.6 | 16 | 929.4 | 37 | 1009.2 |
| — 4 | 853.4 | 17 | 933.2 | 38 | 1012.9 |
| — 3 | 857.2 | 18 | 936.9 | 39 | 1016.7 |
| — 2 | 860.9 | 19 | 940.7 | 40 | 1020.5 |
| — 1 | 864.7 | 20 | 944.5 | 41 | 1024.3 |
| 0 | 868.6 | 21 | 948.3 | 42 | 1028.1 |
| 1 | 872.4 | 22 | 952.1 | 43 | 1031.8 |
| 2 | 876.2 | 23 | 955.8 | 44 | 1035.6 |
| 3 | 879.9 | 24 | 959.6 | 45 | 1039.5 |
| 4 | 883.7 | 25 | 963.5 | 46 | 1043.3 |

*Regla* 2.ª **La corta y aproximada regla de Belville** es la que mejor se adapta á trabajos rápidos en el campo, á saber: súmense solamente las dos lecturas del barómetro; búsquese también la diferencia de las dos lecturas; y luego establézcase la proporción siguiente: **la suma de las dos lecturas es á su diferencia como 55,000 pies es á la altura buscada.**

(*Advertencia del T.* — La regla equivalente á ésta para usar el sistema métrico es la siguiente:

Suma de las alturas barométricas en milímetros : diferencia de las mismas en mm = 16759 : á la altura que se busca en metros.

Pero este procedimiento da errores de alguna magnitud.)

**Corrección por latitud.** Ésta se omite generalmente cuando no se requiere una exactitud grande. Para hacer esta corrección, búsquese primero la diferencia de nivel por las reglas anteriores, luego divídase ésta por el número correspondiente de la tabla siguiente que se halla opuesto á la latitud del lugar. (Si las dos estaciones están á diferentes latitudes, tómese el término medio de ellas.) *Agréguese* el cociente á la dif de altura si la latitud es *menor* de 45°. *Réstesela* si la latitud es *mayor* de 45°. Si la latitud es de 45° no se necesita corrección.

**Tabla de corrección por latitud.**

| Lat. | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 0° | 352 | 14° | 399 | 28° | 630 | 42° | 3367 | 54° | 1140 | 68° | 490 |
| 2 | 354 | 16 | 416 | 30 | 705 | 44 | 10101 | 56 | 941 | 70 | 460 |
| 4 | 356 | 18 | 436 | 32 | 804 | 45 | ∞ | 58 | 804 | 72 | 436 |
| 6 | 360 | 20 | 460 | 34 | 941 | 46 | 10101 | 60 | 705 | 74 | 416 |
| 8 | 367 | 22 | 490 | 36 | 1140 | 48 | 3367 | 62 | 630 | 76 | 399 |
| 10 | 375 | 24 | 527 | 38 | 1458 | 50 | 2028 | 64 | 572 | 78 | 386 |
| 12 | 386 | 26 | 572 | 40 | 2028 | 52 | 1458 | 66 | 527 | 80 | 375 |

(*Advertencia del T.* — Usando la fórmula en metros, como dice nuestra advertencia anterior, se usa esta misma tabla de latitudes; buscando primero la diferencia en metros por la fórmula, luego dividiendo este número de metros por el número correspondiente de la tabla y agregando el cociente á dicha altura en metros si la latitud es menor de 5°, y restándolo, si es mayor.)

## Nivelación por medio del barómetro, ó por la temperatura de ebullición del agua.

*Regla* 3.ª La tabla que sigue, n.º 2, nos pone en capacidad de medir alturas, sea por medio del agua hirviendo, ó por el barómetro. La tercera columna da las alturas aproximadas sobre el nivel del mar, correspondientes á diferentes alturas, ó lecturas del barómetro, y á los diferentes grados del termómetro C, á que el agua hierve al aire libre. Así, cuando el barómetro en una atmósfera tranquila está á 611.6 mm, ó cuando el agua pura de lluvia ó destilada hierve á la temperatura de 93°86, el lugar se halla más ó menos á 1,757 m sobre el nivel del mar, como lo dice la tabla. Es, por tanto, muy fácil encontrar la *diferencia* de altura de dos lugares. Para ello, tómense de la tabla próxima, n.º 2, las alturas opuestas á las dos temperaturas de ebullición, ó á las dos lecturas del barómetro; réstese la opuesta á la lectura más baja, de la opuesta á la lectura más alta, y el residuo será la dif de altura buscada, algo aproximada. Para hacerlo más exacto, súmense las dos lecturas del termómetro y divídase la suma por 2 para obtener el término medio. En la tabla de corrección por temperatura, pág. 329 *b*, tómese el número opuesto á este término medio. Multiplíquese la altura aproximada que se acaba de hallar por este número tabular, y hágase entonces la corrección por latitud si fuere necesario.

Ej. : Supongamos que en la estación baja marca el barómetro 676.6 mm y en la alta 536.9. El termómetro en la baja, 21°1 C; en la alta, 4°4. ¿Cuál es la dif de altura de las dos estaciones?

| | | Altura. |
|---|---|---|
| Las alturas tabulares son : | para 536.9..... | 2,798.0 m. |
| | para 676.6..... | 949.4 m. |
| | Aproximadamente... | 1,848.6 m. |

Para corregir ésta tenemos : $\frac{21.1+4.4}{2} = 12°7$, término medio, y, en la tabla, pág. 329 *b*, corresponde á 12°7... 1.048. Por tanto, $1,848.6 \times 1.048 = 1937.33$ m es la altura aproximada que se busca.

A 21° C el agua pura hierve á medio grado C menos para una altura, por término medio, de 160 m sobre el nivel del mar, hasta una altura de 800 m. A 1,600 m, medio grado en la temperatura de ebullición, corresponde á 164 m. En la tabla 2 el término medio de las dos temperaturas en las dos estaciones, se supone de 0° C, y para esta dif no se requiere corección, por eso el número tabular opuesto á 0° es 1. Esta dif en la *temperatura de ebullición* producida por el cambio de altura no debe confundirse con la de la atmósfera debida á la misma causa. El aire se enfría más á medida que se sube sobre el nivel del mar, y muy aproximadamente, á razón de un grado C por cada 110 m.

**La tabla que sigue** (en lo que se refiere á las alturas barométricas) fué deducida por el autor, del trabajo sobre el barómetro, del teniente coronel R. S. Williamson (U. S. army).

**Tabla 2.** (*Obs. del T.* — Convertida al sistema métrico.) **Nivelación barométrica ó termométrica.** Se supone la temperatura de 0° C. Si no, multip altura barométrica como indica la tabla próxima.

| Temp ebulli-ción. | Lectura baróme-tro. | Altura sobre el mar. | Temp ebulli-ción. | Lectura baróme-tro. | Altura sobre el mar. | Temp ebulli-ción. | Lectura baróme-tro. | Altura sobre el mar. | Temp ebulli-ción. | Lectura baróme-tro. | Altura sobre el mar. |

# EL SONIDO

**La velocidad del sonido** al aire libre y tranquilo se ha determinado por medio de experimentos y es muy aproximadamente de 1,090 pies ó 332 metros por segundo, cuando la temperatura es de 0° centígrado ó 32° F. Para cada grado Fahr de aumento en la temperatura, la velocidad aumenta por segundo (de 15 á 38 cm) según los diferentes autores. Calculando el aumento en un pie por segundo para cada grado F ó sean 55 cm por cada grado centígrado (lo que está bastante de acuerdo con los cálculos teóricos), tenemos á

| | | | |
|---|---|---|---|
| —30° | Fahr | 1,030 | pies por seg |
| —20° | — | 1,040 | — — |
| —10° | — | 1,050 | — — |
| 0° | — | 1,060 | — — |
| 10° | — | 1,070 | — — |
| 20° | — | 1,080 | — — |
| 32° | — | 1,092 | — — |
| 40° | — | 1,100 | — — |
| 50° | — | 1,110 | — — |
| 60° | — | 1,120 | — — |
| 70° | — | 1,130 | — — |
| 80° | — | 1,140 | — — |
| 90° | — | 1,150 | — — |
| 100° | — | 1,160 | — — |
| 110° | — | 1,170 | — — |
| 120° | — | 1,180 | — — |

(*N. del T.* — La tabla siguiente es para temperaturas en C y velocidades en metros.)

| Temperatura del aire en grados C. | Metros por segundo. | Dif. |
|---|---|---|
| —34° | 313.71 | 3.21 |
| —30° | 316.92 | 2.74 |
| —24° | 319.66 | 3.53 |
| —18° | 323.19 | 3.05 |
| —12° | 326.24 | 3.27 |
| — 6° | 329.51 | 3.32 |
| 0° | 332.83 | 2.23 |
| 4° | 335.06 | 3.27 |
| 10° | 338.33 | 3.27 |
| 16° | 341.60 | 3.33 |
| 22° | 344.93 | 2.17 |
| 26° | 347.10 | 3.30 |
| 32° | 350.40 | 3.27 |
| 38° | 353.67 | 2.78 |
| 43° | 356.45 | |

Para las temperaturas intermedias se deduce la velocidad del sonido por una simple proporción. Ej. : ¿Cuál será la velocidad para 18 ½°? Se tendrá que, si para 6 grados de temperatura (22-16) hay una diferencia de 3.33 mets, para 2½ cuánto habrá. Es decir :

6 : 3.33 : : 2½ : $x$, de donde $x$=1.39; luego, 341.60+1.39=342.99 será la velocidad á 18 ½ grados C.

Cuando el aire está en calma la neblina ó la lluvia no afectan apreciablemente los resultados; pero sí los vientos. Los sonidos fuertes parece que andan algo más ligero que los débiles. El alerta de los centinelas se ha oído á través de aguas tranquilas en una noche de calma, á una distancia de 17 kilómetros, y un cañón á 32 kilómetros. Los sonidos producidos á intervalos de $^1/_{10}$ de segundo no se oyen separados sino como ligados unos á otros. Las distancias á que se puede oir un orador colocándose uno enfrente, á un lado ó detrás de él, están más ó menos como los números 4, 3 y 1.

El Dr. Carlos M. Cresson informó al autor que había hallado, por ensayos diferentes en Filadelfia, que en un tubo matriz de gas, de 50 centímetros de diámetro, y de 4.876 mets de largo, colocado en la tierra y cubierto, pero sin contener

gas, y con un codo horizontal de 90° y de 12 mets de radio, el sonido de un tiro de pistola anduvo más ó menos los 4,876 mets en 16 segundos, ó 305 mets por segundo. La llegada del sonido era casi imperceptible; pero se hizo sensible por el movimiento comunicado á un diafragma de papel de seda puesto en la extremidad del tubo.

**Dos botes anclados** á alguna distancia uno de otro pueden servir como línea de base en triangulaciones hechas con objetos situados á lo largo de la costa, hallando primero la distancia entre dichos botes por medio de disparos hechos á bordo de uno de ellos *.

**En el agua la velocidad** es más ó menos de 1,435 mets por segundo, ó como 4 veces la del aire. **En las maderas** es de 10 á 16 veces, y en **los metales** de 4 á 16 veces mayor que en el aire, según algunos autores.

## Dilatación aproximada de los sólidos por el calor; y su temperatura de fusión en F y C †.

* *N. del T.* — Mejor es hacer disparos recíprocos y tomar el término medio de las dist obtenidas.

† **La temperatura de fusión** es muy incierta; damos el promedio de las mejores autoridades.

‡ La tabla enseña que las **contracciones** y **expansiones** de las piedras pueden producir grietas en el invierno, y en verano triturar la argamasa entre las piedras, en bloques gruesos y largos.

Llamando $a_c$, ó $a_f$, al **coeficiente de dilatación lineal** de una substancia = á la fracción de la longitud original en que aumenta ó disminuye una barra prismática de esa substancia para cada cambio en su temperatura de un grado C ó F respectivamente, se tendrá que, como cada grado centígrado vale $^9/_5$ de un grado F y cada F $^5/_9$ de un centígrado, el coeficiente de dilatación para un grado C será los $^9/_5$ del coeficiente para uno F, y á la inversa, el coeficiente para uno F será los $^5/_9$ de uno C; así : $a_c = {}^9/_5\, a_f$; $a_f = {}^5/_9\, a_c$.

El coeficiente de dilatación es prácticamente constante para las temperaturas ordinarias.

**La fuerza** ejercida longitudinalmente por semejante barra en su dilatación ó contracción, es $P = atEF$, donde $a$ = al coeficiente dicho; $t$ = cambio de temperatura en grados; E = al módulo de la elasticidad de la substancia (véase el párrafo 20 y algunos anteriores y posteriores pág. 479); F = área de la sección transversal. **El trabajo** hecho por esta fuerza, estirando ó contrayendo la barra de longitud original L á través de la longitud $l$, es $W = Pl = PLat = a^2t^2EFL$.

**El coeficiente de dilatación superficial** (relación entre el cambio de área de una superficie y su área original) = como á $2a$; y el coeficiente de dilatación cúbica = como á $3a$; suponiendo que el coeficiente de dilatación lineal es el mismo en todas direcciones.

**La madera** común al quemarse produce una temperatura de 427° á 616° C; el carbón vegetal como 1,200° C, y el de piedra como 1,310° C.

---

# TERMÓMETROS

Sean C, R, F, la lectura dada en grados Celsius (centígrados), Reaumur, Fahrenheit, respectivamente. Entonces (véanse tablas 1, 2, 3, más abajo):

$$\mathbf{C} = \frac{5}{4}\,\mathrm{R} = \frac{5}{9}\,(\mathrm{F} - 32)\,;$$

$$\mathbf{R} = \frac{4}{5}\,\mathrm{C} = \frac{4}{9}\,(\mathrm{F} - 32)\,;$$

$$\mathbf{F} = \frac{9}{5}\,\mathrm{C} + 32 = \frac{9}{4}\,\mathrm{R} + 32.$$

Así, sea F = — 40. Entonces $\mathrm{C} = \frac{5}{9}\,(-40 - 32) = -40$. Para **coeficientes de dilatación**, véase pág. 331.

Bajo una temperatura más ó menos de — 37° C (= — 30 R = — 35 F, el termómetro y barómetro mercurial se hacen irregulares. El mercurio comienza á solidificarse más ó menos á — 40 C = — 32 R = — 40 F. Debajo de esta temperatura se usa el alcohol.

## TABLA 1. Fahrenheit, comparado con Centígrado y Réaumur.

# AIRE. — ATMÓSFERA

Se cree que la atmósfera se extiende hasta una altura por lo menos de 72 kilómetros sobre la superficie de la tierra. Es una mezcla de cerca de 79 partes de gas nitrógeno y 21 de gas oxígeno, en volumen; en peso, 77 y 23. Generalmente contiene una traza de agua, de ácido carbónico, de hidrógeno carburado y aun de amoníaco.

**Densidad del aire.** En condiciones normales de 760 mm de presión, á la temperatura de 0° C=32 F y á 45° de latitud, 1.292673 kilogramos por metro cúbico.

Para otras latitudes y elevaciones :

$$\text{Densidad en kilog por metro cúb} = 1.292673 \times \frac{R}{R + 2h} \times (1 - .002837 \cos 2 \text{ latitud})$$

*, en que R es el radio medio de la tierra = 6,366,198 mets; $h$ = altura sobre el nivel del mar en metros. Para otras temperaturas, véase más abajo.

Bajo condiciones normales, pero con .04 partes de ácido carbónico ($CO_2$) en 100 partes de aire, la densidad es=1.293052 kilog por metro cúbico **.

**La presión atmosférica** puede variar en cualquier lugar como 5 cm y más, de un día para otro. La presión media á nivel del mar varía de 745 á 770 milímetros de mercurio, según la latitud y la localidad. Se aceptan 760 mm * como la presión media de la atmósfera y es lo que se entiende por **una atmósfera.** Por **atmósfera métrica** se entiende en toda la Europa Continental un kilog por centímetro cuadrado. La presión disminuye cuando la altura aumenta **. Esta es la razón de por qué una bomba situada en un punto elevado no levanta el agua á tanta altura como en otro más bajo. La presión del aire, como la del agua, es siempre igual en todas direcciones.

Se dice frecuentemente que la **temperatura de la atmósfera baja** (como 1° F para cada 300 pies de altura) **1° C para cada 165 metros** que nos levantamos sobre la superficie de la tierra; pero esto depende de muchas circunstancias y está influído por muchas causas locales. Las observaciones hechas en globo parecen indicar que, después de 300 metros, baja como 1° C por cada 110 m; á los 600 m baja como 1° C por cada 140 m; á 1,200 m, 1° C por cada 165 m, y á 1,600 m, 1° C por cada 192 m.

**Una persona en reposo** necesita para respirar bien de 7 á 10 litros de aire por minuto, los que, ya respirados, vician de 100 á 140 litros de aire. Caminando, ó en un trabajo fuerte, necesita y vicia doble ó triple cantidad. En invierno se necesitan como 140 litros de aire fresco por persona y por minuto para la perfecta ventilación de los cuartos : como 220 en verano. En los hospitales, de 1,000 á 2,000.

**Bajo la superficie** de la tierra, en regiones templadas, se encuentra una **temperatura** tolerable de 10° á 16° C, hasta una profundidad de 15 á 18 m; después aumenta 1° C por cada 30 m más ó menos; todo esto sometido, por supuesto, á considerables cambios por las diversas causas locales. En Hulleras de Rose Bridge, en Inglaterra, á la profundidad de 739 m, la temperatura del carbón es de 34° C; y en el fondo de una perforación hecha en Berlín á 1,271 metros, la temperatura es de 48°3.

**El aire es un conductor lento del calor**; por eso los muros huecos sirven para conservar el calor en las habitaciones y mantenerlas secas. **Se precipita en el vacío** al nivel del mar con una velocidad de 353 m por segundo; es decir, con más ó menos la velocidad del sonido en un aire tranquilo. Véase « Sonido ».

**Como todos los fluidos, el aire se dilata proporcionalmente** á la temperatura, y sus volúmenes varían en razón inversa de las **presiones**, hasta presiones de 52 kilog por cm cuadrado; es decir, hasta presiones como 50 veces mayores que la ordinaria : el aire, en este caso, ocupa un volumen como de $^1/_{50}$ de su volumen primitivo. Las substancias que siguen estas leyes se dice que son **perfectamente elásticas.** Bajo una presión de más ó menos (5½ toneladas por pulg cuad) 862 kilog por cm cuadrado, el aire se hace tan pesado como el agua. Como el aire en la superficie de la tierra está sometido á una presión que equivale al peso de una columna de agua de 10.33 m, se deduce que el aire á 10, 20,

* M. V. Regnault. Memorias de la Academia Real de Ciencias del Instituto de Francia, 1847, tomo XXI.

** Trabajos y Memorias de la Oficina Internacional de pesos y medidas.

30 metros de profundidad, **dentro del agua**, estará comprimido á $^1/_2$, $^1/_3$, $^1/_4$, de su volumen en la superficie.

**Los buzos**, después de algunas experiencias, pueden trabajar varias horas á una presión de 2½ atmósferas; y, sin temor de sufrir mucho, hasta una horas bajo presión de 3 $^1/_2$ atmósferas. No obstante, en el puente de San Luis se trabaj, á una profundidad de 33.70 metros.

**La temperatura del rocío** es aquella (variable) en que el aire deposita suó vapores. La máxima temperatura del aire, al sol, no ha pasado probablemente jamás de 63º C; ni el mayor frío durante la noche de — 59º C.

# VIENTO

**La relación entre la velocidad del viento, y su presión** contra un obstáculo colocado en ángulo recto ú oblicuamente á su dirección, no está bien determinada, y menos aún contra superficies curvas. Probablemente la presión sobre una superficie grande es relativamente mayor que sobre una pequeña. Se supone, generalmente, que varía como los cuadrados de las velocidades.

(*N. del T.* — Para reemplazar la tabla, en unidades inglesas del autor, damos las dos siguientes, tomadas del Manual de los señores Sorna y Castro.)

V = velocidad en m por seg
P = presión en kilogramos.

| V = | 3 | 6 | 9 | 12 | 15 | 18 | 21 | 24 | 27 | 30 | 33 | 36 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| P = | 1.102 | 4.409 | 9.921 | 17.637 | 27.558 | 39.684 | 54.01 | 70.55 | 8 .29 | 110.23 | 133.38 | 158.75 |

## Velocidad y presión del viento.

| Designación del viento. | Velocidad metros por seg. | Presión en kilogs por 1m². | Designación del viento. | Velocidad metros por seg. | Presión en kilogs por 1m². |
|---|---|---|---|---|---|
| Viento poco sensible.. | 2.5 | .765 | Viento muy fuerte.... | 15 | 27.558 |
| — fresco..... | 4.7 | 2.706 | — tempestuoso... | 30 | 110.230 |
| — fuerte..... | 7 | 6.004 | — huracanado ... | 40 | 195.968 |

Se ha observado, en vientos extraordinarios, una presión hasta de 273 kgs.

**Tredgold recomienda que se estime como en 194 kg por metro cuadrado de techo** la presión del viento ejercida sobre éste; pero como los techos se construyen con declives y por consiguiente no soportan la fuerza total del viento, esto es evidentemente demasiado *. Además, generalmente sólo la mitad del techo está expuesta al viento, y algunas veces parcialmente. Es probable que en estos casos la fuerza varíe aproximadamente como los senos de los ángulos de inclinación del techo. Según observaciones hechas en Liverpool en 1860, un viento de 61 km por hora produjo una presión de 68 kg por metro cuadrado contra un objeto, colocado en ángulo recto á su dirección; y uno de 112.65 km por hora (el temporal más fuerte observado en aquella ciudad) una presión de 205 kg por metro cuadrado. En Escocia, durante un temporal violento, la fuerza, registrada por un anemómetro ó medidor de viento excelente, llegó á 219 kg por metro cuadrado. Se dice que en Glasgow se ha observado una presión hasta de 266 kg por metro cuadrado. Los vientos muy fuertes, á menudo *levantan* los techos.

El anemómetro del Colegio de Girard (Filadelfia) se rompió bajo una presión de 205 kg por metro cuadrado, en cuyo momento pasaba un tornado como á distancia de 400 metros.

* El autor cree que 8 lbs por pie cuadrado, ó sean como 39 kg por metro cuadrado para los *techos ordinarios de dos aguas*, ó 16 lbs (78 kg) para los de una sola, es suficiente para la presión del viento.

*N. del T.* — Si se tiene la velocidad del viento en kilómetros por hora, se puede obtener la presión en kg por metro cuadrado, dividiendo el cuadrado de la velocidad en kilómetros por 108. Esto es solamente aproximado.

# LLUVIA Y NIEVE

**La caída anual**, en cualquier lugar, varía mucho de un año á otro, y la relación entre el máximo y el mínimo llega á veces á ser hasta de 2: 1. **Téngase mucho cuidado de los promedios.** En una corriente, para prever sus efectos dañinos, calcúlese el *máximo*, y para explotarla como fuente de distribución, calcúlese el *mínimo* y téngase en cuenta la pérdida por evaporación y filtración.

Los máximos y mínimos deducidos de observaciones de 4 ó 5 años, no merecen fe; se requieren 15 ó 20 años para tener datos aceptables.

(*N. del T.*— La lluvia en mm de algunas ciudades, hoyas hidrográficas y zonas, es la siguiente: Nueva York, 926; Madrid, 490; Hoya del Rhin, 720; la del Sena, 631; la del Ródano, 956; en la ciudad de París, 495.

Dice Henri Mager, en su Hidrología Subterránea, que del Polo Norte al Ecuador se pueden distinguir 5 zonas de lluvias: la zona Polar Artica, limitada por los 60° de latitud norte en Siberia y sobre el continente americano, sus inviernos no son lluviosos.

Después al sur de 60°, limitado por los Pirineos, Alpes Marítimos, Balkanes Altaí y el lago Baikal, una zona en la que llueve en cada estación, pero moderadamente. Más allá y hasta el Trópico de Cáncer, una zona en que no llueve jamás en verano y las lluvias son poco abundantes el resto del año. A esta *zona seca* sigue la *zona de los Monzones*, que por el contrario recibe las lluvias más abundantes de la Tierra; sobre todo en la costa de Arakan, más allá del Ganges, en el fondo del golfo de Bengala, y sobre la costa de Malabar: sobre algunos puntos elevados de esta costa, caen más de 6 metros; en Cherra-Ponjec, á la altura de 1,360 m caen 15 metros de agua. En fin, la *zona de las lluvias periódicas* corresponde á la zona de las calmas ecuatoriales. Más allá del Ecuador, al sur, se repiten las mismas zonas en sentido inverso.

John Marray calcula que la lluvia que cae sobre la Tierra toda, anualmente, equivale á una capa de 970 mm de espesor, que la cubra por entero.)

En Filadelfia, en 1869, año de la mayor sequía conocida en 50 años, cayeron 1075 mm de agua; el 13 de agosto de 1873 cayeron en un día 183 mm; en julio de 1842 cayeron 150 mm en dos horas. En Génova, en Italia, en una ocasión, cayeron 800 mm en 24 horas. En Chicago, en septiembre de 1878, cayeron 24 mm en 7 minutos.

**Cerca de Londres** el promedio de varios años es de 575 mm. En una ocasión cayeron 150 mm en 1½ horas! En los distritos montañosos de los lagos, la cantidad de lluvia es enorme; alcanza algunos años de 4.50 á 6.75 metros; mientras que en los alrededores es apenas de 1 á 1½ metros. En Liverpool el promedio es de 850 mm; en Edimburgo, 750; Glasgow, 550; Irlanda, 900; Madrás, 1170 mm; Calcuta, 1500; Roma, 980. En las montañas al norte de Calcuta han llegado á caer, en los 6 meses de la estación lluviosa, 500 pulgs, ó sean 12m699! En otros distritos montañosos de la India son comunes fuertes caídas anuales de 3 á 6 m. Una lluvia moderada pero firme durante 24 horas alcanza á 25 mm.

**Como regla general, llueve más en los países cálidos que en los fríos** y más también en los lugares elevados que en los bajos. Sin embargo, algunas circunstancias locales producen á veces un efecto contrario y también causan grandes diferencias entre las cantidades caídas en lugares muy cercanos entre sí, como en los distritos de los lagos de Inglaterra arriba mencionados. Algunas veces es difícil encontrar la causa de estas variaciones. En algunas lagunas de Colombia, A. del S. ha sabido el autor que por espacio de algunos meses ocurrieron varias veces 3 ó 4 fuertes lluvias, y durante este tiempo, ni una sola gota cayó en unos cerros como de 305 metros de altura, situados á plena vista y á una dist de 16 kilms.

En otra localidad, lugar casi llano, cayó en la mañana las $^3/_4$ partes de la lluvia caída durante dos años en un lugar distante 3 kilms.

La relación entre la caída de agua y la que llega á **correr como raudal**, varía mucho por la existencia de bosques, por las talas, por la pendiente y naturaleza del terreno en la vertiente, sobre todo por la permeabilidad de aquél, según la época del año, las heladas, etc. El agua que corre puede suponerse que varía generalmente entre .2 y .8 de la lluvia. Las corrientes en regiones [illegible]áreas pierden

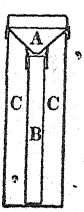
frecuentemente una gran parte de su volumen al atravesar cavernas subtérraneas. Suponiendo una caída de .61 m por año=8351 litros por hectárea y por día, ya que la mitad de la caída de lluvia es aprovechable para el servicio, y que sea suficiente un consumo de 113 litros por cabeza y por día; una milla cuadrada (=259 hectáreas) abastecerá á 19,095 personas, ó un cuadrado de 11.66 m por lado, abastecerá á una persona.

**Una pulgada de lluvia*** equivale á 254 toneladas por hectárea.

Las lluvias más destructoras son generalmente las que caen sobre nieve, debajo de la cual el terreno está helado y no puede absorber el agua.

Algunos ensayos hechos por el autor en diferentes épocas, demuestran que **el peso de la nieve recién caída** varía de 80 á 194 gramos el litro, y parece depender esta diferencia, principalmente, del grado de humedad del aire que atraviesa. En cierta ocasión que cayeron nieve y granizo mezclados hasta la altura de 6 pulgs (15 cent), encontré que su peso era igual á 31 lbs el pie cúbico (499 gramos el litro). Estaba muy seco é incoherente. Un litro de nieve dura, rociada suavemente con agua, puede convertirse como en medio litro de nieve derretida con peso de 650 gr, la cual no se **desliza** en un techo de madera de 30° de inclinación en tiempo de frío. Un bloque de nieve saturado de agua hasta que pese á razón de 45 lbs por pie cúb (721 gramos por litro) resbala justamente en una tabla sin acepillar con 45° de inclinación; en una lisa, acepillada, con 30°, y en pizarra con 18°, aproximadamente. Un prisma de nieve saturado hasta el peso 52 lbs por pie cúbico (833 gramos el litro) de una pulg cuadrada (6.45 cent cuad) de base por 4 pulgs (10 cent) de altura, **soportó un peso** de 7 lbs (3.17 kgs), el cual peso redujo primeramente el prisma en una cuarta parte de su altura. Los ingenieros europeos consideran suficiente **estimar el peso de la nieve** en 29.29 kgs por metro cuad de techo y en 8 lbs por pie cuad (39.06 kgs por metro cuad) la presión del viento, en todo 14 lbs por pie cuad (68.35 kgs por metro cuad). El autor opina que en los Estados Unidos no debe tomarse por peso de la nieve, *menos* de 12 lbs por pie cuad (58.59 kgs por m cuad), en todo 20 lbs por pie cuad (97.65 kgs por m cuad) por la nieve y el viento. No hay peligro en que la nieve se sature en un techo hasta el grado arriba mencionado, porque una lluvia que suministre la cantidad de agua necesaria para producir este efecto, arrastraría también la nieve en la violencia de su caída; pero no nos cabe duda de que en los Estados del Norte la presión de la nieve y del viento unidos alcanza algunas veces y hasta pasa de 20 lbs por pie cuadrado (97.65 kgs por metro cuadrado) de techo. **El límite de las nieves perpetuas** en el ecuador está á la altura de 4,800 m aproximadamente. A la latitud de 45° norte ó sur está más ó menos de la mitad de esta altura, mientras que cerca de los polos está al nivel del mar.

**Medidas de alturas de lluvias. Pluviómetros.** Los envases completamente cilíndricos no se prestan bien para las medidas de las lluvias suaves, aunque



suficientes para dar una apreciable cantidad en una área regular, no llegan á bastante altura para que se las mida con exactitud, á menos que se logre aumentar aquella altura para medirla. La inexactitud en la medida, que siempre es considerable, es á veces demasiado grande con relación á la altura de agua caída.

En su forma más sencilla y usual el pluviómetro (véase figura) consiste esencialmente en un embudo, A, que recibe la lluvia y la eleva á un tubo medidor, B, de menor sección transversal. El embudo deberá tener un borde vertical, y á fin de disminuir la pérdida por evaporización, estar pegado al tubo, y que su extremo inferior sea de pequeño diámetro.

* *N. del T.* — Un centímetro de lluvia equivale á diez millones de kgs por kilom cuadrado.

La profundidad del agua se averigua metiendo hasta el fondo del tubo una varilla de medir, de madera no pulida, en la que se verá hasta qué profundidad se ha mojado. La varilla puede estar graduada ó puede ser comparada con una escala ordinaria en cada observación. El tubo es generalmente de tal diámetro que el área de la sección transversal, menos la de la varilla, es un décimo del área de la boca del embudo. La altura de la lluvia caída será, pues, $^1/_{10}$ de la profundidad medida por la varilla.

*Dimensiones del* **pluviómetro** *oficial de observaciones metereológicas de los Estados Unidos.*

| | | | |
|---|---|---|---|
| A. receptor ó embudo. | | Diámetro 20 | cm |
| B. tubo medidor : | Altura 50 cm | — 6.3 | — |
| CC. aparato de derrame y medida de la nieve. | | — 20. | — |

Tales medidores, con los tubos cuidadosamente hechos de láminas de bronce sin soldadura, cuestan como cinco dólares cada uno; pero un latonero inteligente y cuidadoso, teniendo las dimensiones exactas, puede construir uno de hierro galvanizado, que servirá muy bien, por menos de un dólar.

La **exposición** del aparato tiene un efecto importante sobre los resultados obtenidos. El embudo debe elevarse como 1 m sobre el piso á fin de evitar que caiga en él la lluvia salpicada del mismo piso ó del techo. Si se coloca sobre los techos, éstos deben ser chatos y de 15 m de ancho ó más, y también situar el aparato lo más distante posible de la orilla, pues de lo contrario las corrientes de aire producidas al chocar el viento contra los lados del edificio, llevarán alguna lluvia sobre el medidor.

No debe haber objetos mucho más altos que el aparato cerca de él, pues producen corrientes de aire variables que pueden afectar seriamente sus indicaciones.

Debe tener un depósito C de derrame, para los casos en que el tubo se rebose.

El agua helada en la medida puede reventarla ó averiar el fondo, ó al menos deformarle hasta destruir su exactitud.

**Para medir la nieve** se quita el embudo y se reune la nieve en el aparato de derrame ó en otro envase cilíndrico bastante hondo (para impedir que se vuele), cuya sección transversal se conozca exactamente. La nieve luego se derrite poniéndola en lugar caliente, ó con menos pérdida por evaporización, agregándole una cantidad exactamente conocida de agua tibia. En este último caso dedúzcase de la medida el volumen de agua agregado.

**Equivalencia entre la lluvia y la nieve.** Se supone generalmente que 10 cm de nieve equivalen á uno de lluvia; pero, según varias autoridades, el equivalente puede variar entre 2½ y 34; es decir, como de 30 á 400 gr por litro.

**Los medidores automáticos**, de los que hay varios en el mercado, son bastante costosos, y muchos, aun comprados directamente á los fabricantes, rara vez resultan precisos. Los medidores que tienen un envase con punta registradora no son exactos para fuertes lluvias; los de flotante están limitados en cuanto á la profundidad total que pueden apreciar, y los que pesan el agua caída son afectados por el viento.

# AGUA

El agua pura (como la hervida y destilada) **se compone** de dos gases, hidrógeno y oxígeno, cuya proporción (en volumen) es de 2 á 1, y en peso de 1 de hidróg y 8 de oxíg. Ordinariamente contiene, no obstante, diversas substancias extrañas, como ácido carbónico y otros ácidos; minerales solubles ó substancias orgánicas. Cuando contiene mucha cal, es salobre, *cruda* y no hace mucha espuma con el jabón. **El aire** en su estado ordinario **contiene** (4 granos de agua por pie cúb) como 9 miligramos por litro.

Una columna de agua de 10.33 m equilibra la presión atmosférica á nivel del mar; esto equivale á una columna de mercurio de .76 m.

**Su peso** es como 815 veces el del aire, cuando los dos están á una temperatura

como de 17° C. Como á 4° C tiene su máxima densidad y pesa *un gramo* por centímetro cúbico. Damos en la tabla siguiente lo que pesa á diversas temperaturas.

(*N. del T.* — Hemos ampliado la tabla del autor, agregando los datos en sistema métrico.)

| Temp. Fahr. | Temp. Centíg. | Lbs por pie cúb. | Kg por litros. |
|---|---|---|---|
| 32° | 0° | 62.417 | .9998204 |
| 40° | 4°.44 | 62.423 | .9999165 |
| 50° | 10° | 62.409 | .9996923 |
| 60° | 15°.56 | 62.367 | .9990196 |
| 70° | 21°.11 | 62.302 | .9979785 |
| 80° | 26°.44 | 62.218 | .9966330 |
| 90° | 32°.22 | 62.119 | .9950408 |
| 212° | 100° | 59.700 | .9562984 |

**El peso del agua de mar** es de 64 á 64.27 lbs por pie cúbico ó sea de 1,025.556 klgs á 1,029.560 klgs por metro cúbico.

El agua tiene su **densidad máxima** cuando llega su temperatura un poco más arriba de 39° Fahr (3°89 C). Las mejores autoridades la fijan á los 39°2 F (4° C). A los 39° F ó 3°89 C se dilata tanto por la acción del frío como por la del calor. Cuando la temperatura de 32° (0° C) la reduce á **hielo**, su peso no es sino de 916 gramos por decímetro cúbico y su peso específico .9157 más ó menos según las investigaciones del Sr. L. Dufour. De aquí que, como el hielo se dilata una duodécima parte del volumen que tenía cuando líquido, **la fuerza de dilatación repentina** ejercida en el momento de congelarse es suficientemente grande para rajar los tubos de hierro para el agua; siendo la fuerza probablemente no menos de 2109 kg por cm cuadrado. Ha habido casos de reventarse pilares tubulares fundidos, en puentes de hierro, y de construcciones ordinarias, cuando se han llenado de agua completamente, y después se han congelado expuestos á la intemperie. También el hielo afloja y salta cantidades de roca, por cuyas aberturas ó juntas haya entrado el agua de lluvia ó de corrientes. Los muros de sostenimiento se vuelcan algunas veces, ó por lo menos adquieren combas á causa de la congelación del agua que penetra entre su paramento posterior y el relleno de tierra que sostienen; y los muros que no tienen cimientos de suficiente profundidad, á menudo se levantan por la misma causa.

Se dice que en **un tubo de vidrio de seis milímetros** de diámetro interior, el agua no se congela hasta que la temperatura no se reduzca á — 5° C, y en tubos de un diámetro interior menor que $^1/_4$ de milímetro hasta los 3° ó 4° F (— 16°1 ó — 15°5 C). Tampoco el agua se congela en los ríos de corriente rápida hasta que no esté á mucho menos de 0° C.

**El hielo de anclas**, hallado algunas veces á una profundidad como de 7.61 metros, se compone de una agregación de pequeños cristales ó agujas de hielo congeladas en la superficie del agua libre de corriente rápida, y que probablemente han sido llevadas hacia abajo por la fuerza de la corriente. No se forma debajo del agua helada.

**Como el hielo flota en el agua**, y como un cuerpo flotante desaloja un peso de líquido igual á su peso propio, resulta que un pie cúbico de hielo flotante con peso de 57.2 lbs debe desalojar 57.2 lbs de agua; pero un volumen de 57.2 lbs de agua de un pie cuadrado tiene 11 pulgs de altura, de consiguiente un volumen de hielo flotante de forma cúbica ó paralelepipédica tendrá $^{11}/_{12}$ debajo del agua y sólo $^1/_{12}$ sobre ella; y un pie cuadrado de hielo de cualquier grueso necesita un peso igual á $^1/_{12}$ parte de su peso propio, para sumergirlo hasta la superficie del agua. Sin embargo, en la práctica, esto debe considerarse solamente como una aproximación cercana, porque el peso del hielo varía según las burbujas de aire que contiene.

Se supone generalmente que el agua pura *entra en ebullición* á 100° C al aire libre, al nivel del mar; estando el barómetro á 76 centímetros y más ó menos 0°56 C menos por cada 158 metros sobre el nivel del mar hasta la altura de 1,609 metros. Pero de hecho su temperatura de ebullición varía lo mismo que su punto de congelación, con su estado de pureza, la densidad del aire, material de que esté hecho el envase, etc. En un vaso metálico, el agua puede entrar en ebullición á 210° Fahr (98°89 C), y en uno de vidrio, de 212° á 220° Fahr (100° á 104°44 C); y, si se extrae todo el aire previamente, se requieren 275° Fahr (135° C).

**El agua se evapora** á todas las temperaturas; **disuelve** más substancias que cualquier otro agente, y tiene una capacidad calorífica mayor que cualquiera otra substancia conocida.

**El agua se comprime** á razón de $^1/_{21740}$ partes de su volumen por cada atmósfera de presión (1.033 kg por cm cuad). Cuando se suprime la presión, su elasticidad la hace recuperar su volumen primitivo.

**Su efecto sobre los metales.** La sal contenida en muchas aguas forma depósitos en los tubos metálicos de agua, y en los canales de loza, ó de mampostería, especialmente si la corriente es lenta. Algunas otras substancias hacen lo mismo; obstruyendo la corriente del agua de tal manera, que siempre es conveniente usar tubos de diámetros mayores que los que hubieran sido necesarios sin esta circunstancia. La cal también forma **incrustaciones muy duras en el fondo de las calderas,** que impiden en mucho su eficacia y las hacen más propensas á reventar. Esta agua no sirve para las locomotoras. Hemos visto mencionado que la C.ª de T. C. Southewstern, Inglaterra, evita estos depósitos de cal, en las secciones calcáreas, por medio de la disolución de 1 onza de sal amoníaco en 90 galones de agua (409.91 litros). La sal del agua de mar forma depósitos semejantes en las calderas, como lo hacen también el fango y otros ingredientes impuros.

El agua, cuando está muy pura (como la de lluvia), ó cuando contiene ácido carbónico (como la mayor parte de las aguas), **produce carbonato de plomo** en los tubos de plomo, y como esta substancia es un veneno activo, esta clase de tubos no debiera usarse para tales aguas. Debían substituirse por tubos de plomo estañado.

Pero si también el sulfato de cal se halla en el agua, como sucede muchas veces, no se produce siempre este efecto, y varias otras substancias que generalmente se hallan en el agua, de ríos ó de manantiales, también lo disminuye en un grado más ó menos grande. **El agua dulce corroe más rápidamente al hierro forjado que al fundido**, pero lo contrario parece suceder con **el agua de mar**, aunque esto también afecta el hierro forjado muy ligeramente, de modo que se pueden separar de él con facilidad capas gruesas ó escamas. La corrosión del hierro ó del acero por el agua de mar aumenta con el carbono que contengan. Los cañones de hierro fundido de una embarcación que estuvo sumergida en el agua dulce del río Deleware por más de 40 años, estaban perfectamente libres de oxidación. El general Pasley, que examinó los metales encontrados en los barcos *Royal George* y *Edgar*, el primero de los cuales permaneció sumergido durante 62 años, y el último 133 años, dijo « que el hierro fundido generalmente se había puesto muy blando y en algunos casos parecía plombagina. Algunas balas se calentaron al exponerlas al aire y reventaron en muchos pedazos. El hierro forjado no estaba tan dañado, *excepto en las partes que habían estado en contacto con el cobre ó con el bronce de cañón.* Ninguno de estos cañones estaba muy dañado, con excepción de la parte en contacto con el hierro. Una parte del hierro forjado fué labrado otra vez por un herrero, quien hizo constar que era superior al hierro nuevo ». Cottam dice « que algunos de los cañones fueron transportados cuidadosamente en su estado blando á la Torre de Londres y recuperaron su dureza primitiva con el tiempo (como á los 4 años). Los cañones de bronce de la Mary Rose, que estuvieron sumergidos en el mar durante 292 años, estaban carcomidos considerablemente en algunas partes (donde quizás habían estado en contacto con el hierro). Los cañones viejos, hechos de barras de hierro forjado unidas con aros de hierro, estaban corroídos hasta una profundidad de $^1/_4$ de pulg (seis milímetros) más ó menos; pero probablemente habían estado protegidos por el fango. Las balas de hierro fundido se calentaron hasta el rojo al exponerlas al aire, y se volvieron pedazos como greda seca. »

» Las partes no protegidas de las válvulas de hierro fundido de las compuertas del Canal de Caledonia, se convirtieron en una masa blanda plombaginosa, hasta una profundidad de 18 milímetros en 4 años, pero en las partes que tenían una capa de alquitrán vegetal ordinario, no habían sufrido daño alguno. Este efecto de reblandecimiento del hierro fundido parece ser tan rápido, aun cuando el agua esté solamente algo salobre y aunque no obre sino á intervalos. El mismo efecto se produce en el hierro fundido enterrado en terreno que contenga sal. Algunos tubos de aguas colocados cerca de las dársenas en Liverpool, estaban a los 20 años tan blandos, que podían cortarse con un cuchillo, mientras que otros de la misma clase en terreno más elevado, fuera de la influencia del agua salada, estaban como nuevos, después de 50 años. »

Sin embargo, las observaciones han demostrado **que la rapidez de esta**

**acción depende en mucho de la calidad del hierro**; y que el hierro de un color obscuro, y que contenga mucho carbón combinado mecánicamente, se corroe más rápidamente, mientras que las fundiciones de hierro duro blanco, ó ligeramente gris, permanecen en buen estado mucho tiempo. Algunos pilares de hierro fundido, colocados en el mar, no mostraban deterioro á los 40 años.

**El contacto del hierro con el bronce ó cobre** se dice que produce una acción galvánica, que contribuye á la destrucción rápida, tanto en el agua dulce como en la salada. En algunos fusiles que se recogieron de un navío naufragado y sumergido en agua de mar por espacio de 70 años cerca de Nueva York, las partes de bronce estaban en perfecta condición, pero las partes de hierro habían desaparecido enteramente.

**La galvanización** (dándole una capa de zinc) obra como un preservativo del hierro; pero á expensas del zinc que desaparece pronto, y entonces se corroe aquél. Si se calienta el hierro bien y se le da entonces una capa de **alquitrán mineral caliente**, resistirá á la acción del agua, sea dulce ó salada, por muchos años. El muy importante que el alquitrán esté bien purificado. Una capa así de alquitrán ó de pintura, no impedirá que **algunos moluscos** se adhieran al hierro. El asfalto bien puro es tan bueno como el alquitrán mineral.

**El cobre y el bronce** son muy poco atacados por el agua de mar. *En los tubos de agua de Filadelfia* no se ha encontrado ninguna acción galvánica, en donde se han colocado sunchos de bronce.

**Lo que más perjudica al hierro**, lo mismo que á la madera, es su colocación en lugares donde se seca y se humedece alternativamente. En algunos puntos peligrosos de Long Island Sound, era costumbre enterrar barras redondas de hierro laminado de 10 cm de diámetro más ó menos, para sostener señales. Éstas se gastan muy repetidamente en los puntos donde las toca la alta y la baja marea; á razón de 2½ centímetros más ó menos en 20 años, en cuyo tiempo la barra de 10 cm se reduce á 5 cm en las partes mencionadas. Una capa delgada de barniz de brea mineral, aplicada con esmero, protege al hierro, del mismo modo que á los tubos de agua, etc., durante mucho tiempo, debajo del agua dulce especialmente, pero también enterrados en la tierra.

El ácido sulfúrico contenido en el agua de las minas de carbón corroe los tubos de hierro rápidamente.

**En el agua dulce de algunos canales**, las lanchas de hierro han estado en servicio constante de 20 á 40 años. **La madera permanece bien** durante siglos debajo del agua, sea dulce ó salada, si no está expuesta á ser gastada por la acción de las corrientes ó destruída por los insectos marítimos.

**El agua de mar difiere un poco en peso en diferentes lugares**, pero en el mismo lugar varía de modo inapreciable á diversas profundidades y puede suponerse generalmente de 64 lbs por pie cúbico (1.025 kilgs por decímetro cúbico). Su exceso de peso sobre el agua dulce es principalmente sal ordinaria.

**El agua de mar se congela á** 27° Fahr ( — 2°8 C). El hielo es dulce, pero (especialmente á bajas temperaturas) puede encontrarse salmuera en el hielo.

Una cucharilla de té, llena de alumbre en polvo, echada en un tobo de agua sucia, y bien revuelta después, la purifica generalmente en un par de horas lo suficiente para poderla beber. Si se cava un hoyo de 1 á 1½ m de profundidad en arena de playa de mar, el agua que se obtiene es por lo común suficientemente dulce para lavar en ella con jabón, y hasta se puede beber. Se dice también que el agua puede conservarse en buen estado por muchos años, echando en el envase que lo contiene 1 onza de óxido negro de maganeso por cada galón de agua (3.78 litros).

*Se dice que el agua depositada en estanques de zinc*, ó la que corre por tubos de hierro galvanizados interiormente, se hace venenosa rápidamente por la formación de sales de zinc solubles; y se recomienda dar una capa de barniz de asfalto á las superficies de zinc para evitar esto. Sin embargo, en la ciudad de Hartford (Conn.) se adoptaron tubos de hierro para el servicio en 1855, galvanizados por dentro y por fuera, recomendados por los comisionados de las aguas, y que han estado en uso hasta ahora. También se han usado bastante en Filadelfia y otras ciudades. En muchos hoteles y otros edificios de Boston, los tubos de latón (brass) (bronce) sin empates de la *American Tube Works en Boston*, han estado en uso por muchos años y han dado resultados satisfactorios. Se dice que el agua más potable puede guardarse durante años en envases de bronce sin que produzca ningún resultado dañino.

**La acción del plomo** sobre algunas aguas (hasta sobre aguas puras) es alta-

mente venenosa. Esto es, sin embargo, muy variable : un ingrediente nocivo puede estar acompañado por otro que neutralice su acción. Las materias orgánicas, sean vegetales ó animales, son dañinas. El ácido carbónico, no estando en exceso, es inofensivo.

**El hielo puede ser tan impuro** que sea peligroso beber el agua que de él se obtenga.

**La idea popular de que el agua caliente se congela con más rapidez que el agua fría** con aire á la misma temperatura, es errónea.

# MAREAS

**Las mareas** son las elevaciones y descensos muy conocidos de la superficie del mar y de algunos ríos, causados por la atracción del sol y de la luna. Hay dos elevaciones ó mareas altas y dos descensos ó mareas bajas cada 24 horas y 50 min (**un día lunar**); haciendo un término medio de 6 horas, 12½ minutos entre las mareas altas y bajas. Estos intervalos están, sin embargo, **sujetos á grandes variaciones**, como también las alturas de las mareas; y no solamente en diferentes lugares, sino en uno mismo. Tales irregularidades son debidas á la forma de la costa, la profundidad del agua, el viento y otras causas. Generalmente en la luna nueva y en la luna llena, ó más bien un día ó dos después (ó dos veces en cada mes lunar, á intervalos de dos semanas), la marea sube y baja más que en otro tiempo; ésta se llama **marea fuerte**. Un día ó dos después de los *cuartos de la luna*, sube y baja menos que en otro tiempo, y ésta se llama **marea muerta**. De la marea muerta á la marea fuerte, suben y bajan diariamente más, y viceversa. **La época de la marea alta** en cualquier lugar es generalmente dos ó tres horas después que la luna ha pasado por el meridiano superior ó inferior del lugar; y se llama el *establishment* del lugar, porque, cuando se establece este tiempo, la época de la alta marea en cualquier otro día puede hallarse por aquél en muchos casos. La altura total de la marea mayor es *generalmente* de 1½ á 2 veces la de la marea muerta. Cada marea alta ocurre como 24 minutos más tarde que la precedente. Lo mismo sucede con la baja.

# EVAPORACION, FILTRACION Y MERMA

**La evaporación total de la superficie de las aguas** expuestas á los efectos naturales del aire libre, es mayor en el verano que en el invierno; sin embargo, es muy perceptible aún en tiempo muy frío. La evaporación es mayor en aguas poco profundas que en hondos depósitos, aunque el sol penetre también hasta el fondo y lo caliente. Es mayor en el agua corriente que en la estancada; y mayor cuando hay viento que cuando hay calma. Es probable que la pérdida media, producida solamente por la evaporación en un estanque de una profundidad mediana, exceda rara vez de 7½ mm por día, durante los 3 meses cálidos (junio, julio y agosto) en cualquiera parte de los Estados Unidos. O 2½ mm durante los 9 meses más fríos, excepto en los Estados del Sur. Estos dos promedios darían un término medio diario de $3^{3}/_{4}$ mm ó una pérdida total de 1.39 m por año. Probablemente es de 1.066 á 1.219 m.

**El resultado de algunos ensayos hechos por el autor en países tropicales** demuestra que los estanques hechos con una greda dura y con el agua á 2 m 43 de profundidad, expuesta todo el día á un sol muy caliente, mermaron durante la estación seca exactamente 5 cent en 16 días ó $3^{1}/_{3}$ mm por día, mientras que la evaporación de un vaso de agua era de 6 mm por día. El aire de aquella

región está muy cargado de humedad y el sereno es muy fuerte. Todos los días, durante estos ensayos, las indicaciones del termómetro eran de 46° á 51° C en el sol. La evaporación total por año en algunas partes de Inglaterra y Escocia se dice que es de 588 á 965 mm; en París, 863 mm; en Boston Mass, 812 mm, y en muchos lugares de los E. U. de 761 á 914 mm. Esta última daría un término medio diario de 2½ mm para todo el año. Estos datos, sin embargo, son de poco valor si no están acompañados de referencias sobre las circunstancias en cada caso, tales como profundidad, superficie expuesta, tamaño y naturaleza del envase, ó estanque que contiene el agua, etc. Algunas veces la evaporación total anual de una sección de un país excede á la lluvia caída y viceversa.

**En los canales, estanques, etc.**, se acostumbra unir la pérdida por la evaporación á la de la filtración. Esta última es la absorbida por la tierra, y de la cual una parte pasa enteramente á través del relleno (si éste existe), y si es en pequeña cantidad, puede ser evaporada por el sol y el aire, tan luego como salga fuera, de tal manera que no se percibe; pero, si la cantidad filtrada es suficiente, se nota la *merma*.

**E. H. Gill, ingeniero civil, dice que la evaporación y filtración media de los canales Sandy y Beaver, Ohio**, de 11 m 58 de ancho en la superficie, 7 m 92 en el fondo y 1 m 219 de profundidad, no es sino de 228.8 lit por km y por minuto *durante una estación seca*. La superficie expuesta del agua es de 11580 m² por km; y por tanto, para perder con esta superficie 228.8 lit por km y por minuto, ó sean 329.443 m³ por km, y por día de 24 horas, la cantidad perdida debe ser de .028 m en profundidad por día. Además, con las dimensiones arriba dadas resulta que un kilómetro de canal contiene 11885 m³; por consiguiente, tendríamos $\frac{11885}{329.443} = 36$ días. Las observaciones hechas en tiempo cálido en 35.40 km del canal Chenango, N. Y., de 12.19, 8.53 y 1.21 m, dieron por resultado 1.152 m³ por km y por minuto ó cinco veces el resultado anterior. En esta proporción se vaciaría el canal en 8 días más ó menos. Además hubo una merma excesiva por las compuertas del canal que ascendió á 383 lit por km y por minuto. En otros acueductos y compuertas alcanzaron las pérdidas á 334 lit por km y por minuto. En el canal Chesapeake y Ohio, de 15.23, 9.75 y 1.82 mts, Fish, ingeniero civil, calculó la evaporación y filtración durante dos semanas de tiempo cálido equivalente á toda el agua del canal. **El profesor Rankine presume que es de 5 cm diarios la pérdida por evaporación y filtración del lecho del canal en los canales ingleses.** J. B. Jervis, I. C., estima la pérdida por evaporación, filtración y merma á través de las compuertas del canal primitivo de Erie (12.91, 8.53 y 1.21 m) en 1.758 m³ por km y por minuto, ó sean 2,533 m³ por día y por km. Siendo la superficie del agua de 12,190 m² en un kilómetro, la pérdida diaria será, por consiguiente, de $\frac{2533}{12190} = 207$ mm de profundidad más ó menos.

**En la división Delaware de los canales de Pensilvania**, cuando la provisión ordinaria está temporalmente en una gran extensión, el agua desciende de 101 á 203 mm por día. La filtración es, por supuesto, mayor en los terraplenes que en las cortadas. En algunos de nuestros canales, la profundidad del agua llega á hacerse muy considerable en los grandes rellenos ó terraplenes, cuando por motivos de economía no se echa la tierra del relleno bajo el lecho del canal en capas á nivel, sino que se le deja formar por sí misma su talud natural. En un lugar por lo menos del canal Ches y Ohio, en el cual está un lado formado con la superficie natural de roca vertical, esta profundidad es de 12 m 19. Estas profundidades aumentan mucho la filtración, especialmente cuando, como sucede en muchos casos, no se reviste el terraplén con arcilla; hay otras razones para no recomendar esta práctica.

**El término medio de las pérdidas totales en los estanques de profundidad moderada**, en caso de que se construyan cuidadosamente los diques de tierra y se dejen para que el tiempo los consolide bien, no excederá de 12 á 25 mm por día; pero en los estanques nuevos la pérdida es ordinariamente mayor.

**La pérdida en las zanjas ó canales de áreas pequeñas** es mucho mayor que en los canales navegables, de modo que en los grandes canales surtidores ó de alimentación, sólo se pierde una cantidad relativamente pequeña del agua que les entra.

# MECANICA. LA FUERZA APLICADA Á LOS CUERPOS RIGIDOS

En las páginas subsiguientes nos proponemos aclarar algunos principios elementales de mecánica. Los primeros artículos están dedicados principalmente al estudio de la **materia en movimiento**; pues aunque el conocimiento de ésta tal vez no sea absolutamente necesario para la adquisición del conocimiento *práctico* de aquellos principios de Estática de aplicación tan extensa para el ingeniero civil, sin embargo le serán un auxiliar importante para sus inteligentes apreciaciones.

**Art. 1 (a). La mecánica** es la ciencia que trata de los efectos de la fuerza sobre la materia.

Esta definición tan lata de la palabra « Mecánica » incluye no sólo la hidrostática, la hidráulica, la neumática, etc., sino también la electricidad, la óptica, la acústica y ciertamente todos los ramos de la Física; pero nosotros nos circunscribimos principalmente á considerar la acción de las fuerzas extrañas sobre los cuerpos que suponemos *rígidos*, es decir, que no cambian de forma.

**(b)** * La mecánica se divide en tres partes, á saber :

**La Cinemática** ó el estudio de los *movimientos* de los cuerpos, sin referencia á las causas del movimiento, y

**La Dinámica** ó el estudio de las fuerzas y sus efectos.

**La Estática**, que considera los casos en que fuerzas iguales y opuestas neutralizan sus efectos.

**Art. 2** (a). **Materia ó substancia** puede definirse « todo aquello que ocupa un espacio », como los metales, piedras, madera, agua, aire, vapor, gas, etc.

**(b) Cuerpo** es una cantidad cualquiera de materia que en realidad está más ó menos del todo separada de otra, ó que la consideramos como si lo estuviera.

Así pues, una piedra es un cuerpo, ya sea que se encuentre atravesando el aire en su caída, situada en el terreno ó formando parte de un muro. El muro es también un cuerpo, y podemos considerar que también lo es una parte cualquiera de él, como un pie cúbico, un metro cúbico, un centímetro cúbico, etc. La tierra y los otros planetas son cuerpos así como sus más pequeños átomos.

Una serie de carros puede considerarse como un cuerpo, del mismo modo que cada carro, cada rueda, eje ú otra parte cualquiera del carro; cada pasajero, etc., etc.

De la misma manera, el océano es un cuerpo, y podemos considerar como tal, á voluntad, cualquiera parte de él, como un metro cúbico, una bahía determinada, una gota, etc.

**(c)** Pero en lo que sigue consideraremos especialmeente (como ya se ha dicho) los cuerpos *rígidos*, es decir, aquellos que no están sujetos á cambios de formas : como la contracción, el alargamiento, la ruptura ó la penetración por otro cuerpo. Todos los cuerpos existentes están más ó menos sujetos á alguno de estos cambios de forma, es decir, que ningún cuerpo es en *realidad* absolutamente rígido; pero podemos, por conveniencia, suponer que existen semejantes cuerpos, porque muchos de ellos son tan rígidos que en las circunstancias ordinarias experimentan poco ó ningún cambio de forma, y porque estos cambios, cuando ocurren, deben estudiarse en un capítulo aparte titulado « Resistencia de Materiales ».

**(d)** Al mismo tiempo que los cuerpos son considerados como incapaces de cambios de *forma*, es igualmente importante que se los considere como *susceptibles* de cambiar de posición como un todo (no compuesto de partes). Así pues, pueden volcarse y hacerse girar horizontalmente y en cualquiera otra dirección; moverse en cualquiera línea recta ó curva, girando ó no, alrededor de un punto situado en el mismo cuerpo. En suma, son capaces de *movimiento* como un *todo*.

**Art. 3** (a). **El movimiento** de un cuerpo es su cambio de lugar con relación á otro cuerpo ó algún punto real ó imaginario que *consideramos* (por conveniencia) fijo ó en reposo. Así, cuando una piedra cae de un techo al suelo, su posición con

* *N. del T.* — El autor trae dos diversas acepciones para los términos *kinematics* y *kinetics* que no existen en español, así es que nos ha parecido mejor establecer la división de la mecánica como sigue.

relación al techo cambia constantemente, del mismo modo que con relación al suelo y á cualquier punto dado en la pared, y entonces decimos que la piedra está animada de un *movimiento relativo con respecto á uno de aquellos cuerpos* ó á cualquier punto considerado en ellos. Pero si dos piedras, A y B, caen del techo al mismo tiempo y llegan al suelo en el mismo instante, decimos que aun cuando cada una se mueve, con relación al techo y al suelo, no tienen sin embargo *movimiento relativo* entre sí, es decir, que se hallan en *reposo* la una con relación á la otra, pues sus posiciones relativas no cambian, es decir, que cualquiera que haya sido la dirección y la distancia á que se encontraba la piedra A de la piedra B en el momento de la salida, ha permanecido en una misma dirección y á la misma distancia de B, durante todo el tiempo de la caída. De la misma manera, el techo, la pared y el suelo están en reposo relativo entre sí, no obstante estar en movimiento con relación á la piedra que cae. Igualmente están en movimiento con relación al Sol, debido á la rotación diurna de la tierra alrededor de su eje y á su movimiento anual alrededor del Sol.

(b) Si un hombre camina hacia atrás en la parte superior de un tren de carga con la misma velocidad con que el tren se mueve hacia adelante, dicho hombre estará en *movimiento* con relación al tren; pero si lo consideramos como un todo separadamente del conjunto, se hallará en reposo con relación á los *edificios*, etc., cercanos, pues para un espectador que se encuentra parado á una pequeña distancia de la vía, lo verá constantemente frente á la misma parte del edificio, etc. Si el hombre cesa de caminar sobre el tren, entonces estará fijo ó en reposo con relación al *tren*, pero al mismo tiempo en *movimiento* con relación á los *edificios*, etc., que se encuentran á su alrededor, pues el espectador entonces lo verá moverse con el tren.

(c) Como no conocemos ningún punto absolutamente fijo en el espacio, no podemos decir cuál es el movimiento *absoluto* de un cuerpo. Por consiguiente, no sabemos de nada que esté en *reposo absoluto* y podemos decir con certeza que *todos* los cuerpos están con movimiento.

**Art. 4 (a). La velocidad** de un cuerpo en movimiento es la *relación* de su movimiento. Un cuerpo (como un tren de ferrocarril) se dice que se mueve con **velocidad constante**, cuando las *distancias* que recorre en *tiempos iguales* son *iguales entre sí*, por más pequeños que se tornen estos tiempos.

(b) La velocidad se expresa por la distancia recorrida *durante un tiempo dado*. Así, pues, si un tren de ferrocarril que se mueve con velocidad constante, recorre diez millas en media hora, podemos decir que su velocidad durante ese tiempo es de 20 millas (esto es, que se mueve á razón de 20 millas por hora ó 105,600 pies por hora ó 1,760 por minuto ó $29\frac{1}{3}$ pies por segundo. O, si se quiere, podemos decir que se mueve á razón de 10 millas cada *media* hora ú 88 pies en *tres* segundos, etc. Pero en general es más conveniente fijar la distancia que recorra en la *unidad* de tiempo, como en *un* día, *una* hora, *un* segundo, etc.

(c) Si de dos trenes, A y B, que se mueven con velocidad constante, A recorre 10 kilómetros en media hora, y B 10 kilómetros en un cuarto de hora, las velocidades serán

A, 20 kilómetros por hora;
B, 40 kilómetros por hora.

En otras palabras, la velocidad de un cuerpo (que puede definirse *la distancia* recorrida en un *tiempo* dado) está en *razón inversa* del tiempo que se emplea en recorrer una distancia *dada*.

(d) **Por unidad de velocidad** se entienden las que de común acuerdo se toman iguales á la *unidad* ó á *uno*. Donde se usan medidas inglesas, la unidad de velocidad generalmente adoptada es un pie por segundo.

(e) Cuando decimos que un cuerpo tiene una velocidad de 20 kilómetros por hora, 10 metros por segundo, etc., no es necesario que recorra precisamente 20 kilómetros ó 10 metros, pues puede no tener suficiente tiempo para ello. Queremos decir simplemente que se está moviendo á *razón* de 20 kilómetros por hora ó de 10 metros por segundo, etc., de manera que, si *continua* moviéndose con la misma velocidad durante una hora ó un segundo, recorrerá 20 kilómetros ó 10 metros.

(f) Cuando la velocidad *aumenta*, se dice que el movimiento se **acelera**. Cuando *disminuye*, se dice que se **retarda**. Si la aceleración ó el retardo es exactamente proporcional al tiempo, es decir, cuando durante cualquiera y en cada intervalo igual de tiempo tiene lugar el mismo cambio, el movimiento es *uniformemente* acelerado ó retardado. Cuando es de otro modo, se dice que es *variable*.

(g) Un cuerpo puede estar animado al mismo tiempo por **dos ó más veloci-**

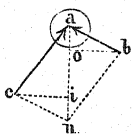
**dades independientes** que es necesario considerar; por ejemplo, una bala disparada verticalmente hacia arriba por un fusil y que luego cae de nuevo á tierra, está animada durante todo el tiempo de su elevación y descenso : (1.º) de la velocidad de *ascensión uniforme* con la cual parte de la boca; y (2.º) la velocidad continuamente *acelerada de descenso* dada por la gravedad que obra sobre ella durante todo el tiempo. Su velocidad *resultante* (ó aparente) en cualquier momento, es en este caso la diferencia de estas dos.

Así, inmediatamente después que parte del fusil, la velocidad de descenso comunicada por la gravedad es muy pequeña y la resultante de la velocidad es, por lo tanto, de ascensión y casi igual á la totalidad de la velocidad de ascenso producida por la pólvora. Pero después de un instante la velocidad descendente (aumentando constantemente) se hace igual á la velocidad ascendente; esto es, su diferencia ó la resultante de la velocidad desaparece y la bala se detiene en ese momento, pero su velocidad descendente continúa aumentando é inmediatamente se hace un poco mayor que la velocidad ascendente, luego se hace mayor cada vez, hasta que la bala cae á tierra. En este instante su velocidad resultante es:

$$= \left\{ \begin{array}{c} \text{La velocidad descendente que hubiera} \\ \text{adquirido al caer } \textbf{durante todo} \\ \textbf{el tiempo de su ascenso y descenso.} \end{array} \right\} - \left\{ \begin{array}{c} \text{La velocidad uniforme ascen-} \\ \text{dente comunicada por} \\ \text{la explosión de la pólvora.} \end{array} \right\}$$

Hemos hecho aquí omisión de la resistencia del aire, que de seguro retarda el ascenso y descenso de la bala.

(**h**) Para mayor claridad supongamos que *abnc* es una balsa impelida en la dirección *ca* ó *nb*. Que un hombre camina sobre dicha balsa con velocidad uniforme del extremo *n* al extremo *c* mientras que la balsa es arrastrada (con una velocidad uniforme un poco mayor que la del hombre) en la dirección *nb*. Por consiguiente, cuando el hombre llega al punto *c*, este punto se habrá trasladado al punto que



ocupaba *á* cuando él partió. La resultante del movimiento del hombre con relación al lecho del río ó á un punto de la ribera ha sido por consiguiente *na*. El movimiento en ángulo recto á *na* producido por su caminata en la balsa es *ic*, pero el debido al impulso de aquélla es *ob*. Estos dos son iguales y opuestos. Por consiguiente, la *resultante* de su movimiento en ángulo recto á *na* es nula; y por tanto, no se separa de la línea *na*. El paseo lo traslada á una distancia igual á *ni*, en la dirección *na*, y el impulso de la balsa lo hace recorrer una distancia igual á *ia*. La suma de estas dos es *na*.

(**i**) Todos los movimientos que les vemos comunicados á los cuerpos, no son sino *cambios* ó variaciones de sus movimientos *absolutos* desconocidos. Por conveniencia debemos limitar nuestra atención á uno ó más de estos cambios prescindiendo de los otros.

Así, en el caso de la bala disparada hacia arriba por un fusil (véase (**g**) atrás) podemos omitir su movimiento uniforme ascendente y considerar únicamente su movimiento acelerado constante descendente, producido por la acción de la gravedad; ó como más se acostumbra : considerar sólo el movimiento *resultante, aparente*, que primero se efectúa hacia arriba y después hacia abajo. En ambos casos prescindimos de los movimientos de la bala causados por los diferentes movimientos de la Tierra en el espacio.

**Art. 5 (a). La fuerza es « la causa del cambio del movimiento ».** Supongamos una bola perfectamente lisa colocada sobre una superficie perfectamente dura, sin frotamiento y á nivel, y supongamos que no existe la resistencia del aire. Para sólo *mover* la bola horizontalmente (esto es, para ponerla en movimiento ó para modificar su estado de movimiento) debe obrar alguna fuerza sobre ella. Si dicha bola estaba ya en movimiento, no podríamos retardarla, acelerarla, ni separarla de su trayectoria, sin aplicarle alguna fuerza, porque, como se establece en **la primera ley de Newton sobre el movimiento, « todo cuerpo continúa en su estado** de reposo, ó de movimiento en línea recta, á menos que obren sobre él otras fuerzas que cambien aquel estado».

Por otra parte, si una fuerza obra sobre un cuerpo, el movimiento de éste debe experimentar cambios.

**(b) Fuerza es la acción que entre dos cuerpos tiende á separarlos ó á unirlos.** Por ejemplo, cuando una piedra cae al suelo, explicamos el hecho diciendo que una fuerza (la gravedad) tiende á juntar la piedra y la tierra.

La atracción magnética y eléctrica y la fuerza adherente que obran entre las partículas de un cuerpo, son otros ejemplos de fuerzas *atractivas*.

**(c) Fuerzas aplicadas por contacto.** En la práctica le comunicamos fuerza á un cuerpo (B) por el contacto entre él y otro cuerpo (A) que tiene tendencia á moverse hacia B. Así se pone en acción una fuerza *repulsiva* entre los dos cuerpos (de un modo que no podemos comprender), y esta fuerza impele á B hacia adelante (ó en la dirección en que tiende á moverse A) y reacciona empujando á A hacia atrás, *disminuyendo* así su tendencia hacia adelante *.

Si, por ejemplo, se coloca una piedra sobre el suelo, ella tiende á moverse hacia abajo; pero no lo hace porque la tierra la rechaza ejerciendo una fuerza repulsiva precisamente igual á la fuerza con que la gravedad tiende á atraerlas.

De la misma manera, cuando tratamos de suspender con nuestra mano un peso, lo hacemos comunicándole á la mano una tendencia á moverse hacia arriba. Si la mano resbala sobre el peso, esto mueve la mano rápidamente hacia arriba antes de que nuestra voluntad pueda evitarlo. Pero puede suceder que la fuerza repulsiva engendrada por el contacto entre la mano (dirigiéndose hacia arriba) y el peso mueva á este último hacia arriba á pesar de la fuerza de la gravedad, é impulse la mano hacia abajo disminuyendo en mucho la velocidad ascensional que de otra manera tendría. Quizás del **esfuerzo**, del cual tenemos conciencia en dichos casos, es que derivamos nuestras nociones sobre la **fuerza**.

Cuando una bola de billar A, en movimiento, choca con otra B, que se halla en reposo, á la tendencia de A á continuar moviéndose, hacia adelante, opone resistencia una fuerza repulsiva que se ejerce entre A y B. Esta fuerza empuja á B hacia adelante y á A hacia atrás disminuyendo su anterior velocidad. Como se explica en el art. 23 (*a*), la fuerza repulsiva no existe en ninguno de los dos cuerpos antes de encontrarse.

(**d**) La fuerza repulsiva nacida así del contacto de dos cuerpos sólo continúa obrando mientras permanecen en contacto y sólo durante el tiempo que tienden (por alguna causa extrema) á unirse estrechamente. Pero está generalmente ó siempre acompañada de una fuerza repulsiva adicional debida á la *compresión* de las partículas de los cuerpos y á la tendencia que tienen á volver á su posición primitiva. Esta fuerza repulsiva *elástica* puede continuar obrando después que ha cesado la tendencia á la compresión.

(**e**) **Las fuerzas obran por atracción ó repulsión.** Cuando un peso está suspendido de un gancho atado al extremo de una cuerda, la gravedad *atrae* el peso; el peso *arrastra* el gancho, y el gancho *tira* de la cuerda, y cada una de estas acciones está acompañada de su correspondiente y opuesta « reacción ». Cuando dos cuerpos chocan, cada uno empuja al otro, generalmente por muy corto tiempo.

**(f) Igualdad de las acciones y reacciones.** Una fuerza ejerce siempre acciones *iguales* sobre dos cuerpos entre los cuales obra. Así, la fuerza (ó atracción) debida á la gravitación, cuando se ejerce entre la tierra y una piedra, atrae la tierra hacia arriba con la misma fuerza con que atrae la piedra hacia abajo, y la fuerza repulsiva que actúa entre una mesa y unapiedra que reposa sobre ella, impele la mesa y la tierra hacia abajo con la misma intensidad con que rechaza la piedra hacia arriba. Este es el hecho consignado por **Newton en su tercera ley del movimiento**, es decir, que « para cada acción hay siempre una reacción igual y contraria ». Con respecto á las medidas de las fuerzas, véanse los artículos 11, 12 y 13.

Si una bala de cañón en su carrera corta una hoja de un árbol, decimos que la hoja ha reaccionado contra la *bala*, con la misma fuerza precisamente con que la *bala* ha obrado contra la *hoja*. Esta fuerza era suficiente para cortar una hoja, pero no para detener la bala. Un buque de guerra al tropezar contra una canoa, ó el puño de un pugilista al pegarle á su contrario en la cara, recibe un golpe tan violento como el que da; pero el mismo golpe, que volvería ó sumergiría una canoa,

---

* Generalmente expresamos todo esto diciendo simplemente que A empuja á B hacia adelante, y esto basta en la práctica; pero es bueno reconocer que es una expresión de mera conveniencia que no establece de una manera exacta los hechos y que cada fuerza *necesariamente* se compone de *dos* impulsos iguales y opuestos ejercidos entre dos cuerpos.

no afecta *apreciablemente* el movimiento de un buque, y el golpe que puede dañar seriamente la nariz, boca ú ojos, no produce efectos semejantes en los nudillos de las manos.

La resistencia que un estribo opone á la presión de un arco, ó un muro de sostenimiento á la presión de las tierras apoyadas detrás de él, no es mayor que las presiones mismas; pero el estribo y el muro se han hecho por razones de seguridad *capaces* de soportar presiones mucho mayores en caso de que circunstancias accidentales las produzcan.

(g) En la mayor parte de los casos prácticos **tenemos que considerar uno solo** de los dos cuerpos entre los cuales obra una fuerza. De aquí que por conveniencia comúnmente hablamos, como si la fuerza estuviese dividida en *dos* fuerzas iguales y opuestas, una para cada uno de los dos cuerpos, y limitamos nuestra atención á *uno* de los cuerpos y á la fuerza que obra sobre él sin ocuparnos del otro. Así, podremos hablar de la fuerza del vapor de una máquina como que obra sobre el *émbolo* y prescindir de la presión igual y opuesta, que obra contra la cabeza del cilindro ó cuerpo de bomba.

(h) El punto de un cuerpo al cual, teóricamente, se le aplica una fuerza, se llama **punto de aplicación**. En la práctica no se puede aplicar fuerza á un punto de acuerdo con el significado científico de esta palabra, sino que tenemos que aplicarla distribuída sobre una *área* (algunas veces muy grande) del cuerpo. Al presente vamos á suponer que la línea de acción de la fuerza pasa por el centro de gravedad del cuerpo y es perpendicular á la superficie en el punto de aplicación.

**Art. 7 (a). Aceleración.** Cuando una fuerza que no encuentra resistencia obra sobre un cuerpo y lo pone en movimiento (esto es, le comunica velocidad) en la dirección de la fuerza, esta velocidad *aumenta* mientras la fuerza continúa obrando; y en cada intervalo igual de tiempo (si la fuerza permanece constante) aumenta igual cantidad la velocidad.

Así, si se deja caer una piedra, la fuerza de la gravedad le comunica, en el primer intervalo de tiempo, una pequeña velocidad descendente; en el próximo intervalo igual de tiempo le comunica una segunda velocidad, igual á la primera, de manera que, al fin del segundo intervalo de tiempo, la velocidad de la piedra es el doble de la que tiene al fin del primero, y así sucesivamente. Podemos dividir el tiempo en intervalos iguales tan pequeños como querramos. En cada uno de dichos intervalos la fuerza constante * de la gravedad comunica á la piedra un incremento de velocidad igual.

Este incremento de velocidad se llama *aceleración*. Cuando se lanza un cuerpo verticalmente *hacia arriba*, la aceleración descendente de la gravedad obra como *fuerza retardatriz* del movimiento ascendente. Cuando una fuerza obra de esta manera, *contra* el movimiento de que se trata, su aceleración se hace *negativa*.

**Art. 8 (a). La aceleración** es el aumento de velocidad que tiene lugar en *un tiempo dado;* como *un* segundo, por ejemplo.

(b) **La unidad de aceleración** es el aumento de una unidad de velocidad en cada unidad de tiempo, como, por ejemplo, un pie por segundo en cada segundo, ó un metro por segundo en cada segundo (un metro por segundo, *por segundo*).

(c) Para una *aceleración dada*, las aceleraciones *totales* son, por supuesto, proporcionales á los tiempos durante los cuales la velocidad tiene dicha aceleración.

**Art. 9 (a). Leyes de las aceleraciones.** Supongamos dos barras de hierro: una (á la cual llamaremos A) de longitud doble que la otra (*a*), colocadas cada una sobre un plano perfectamente horizontal y sin frotamiento, de manera que, al moverlas horizontalmente, no encontremos oposición de ninguna fuerza que tienda á detenerlas. Ahora, apliquese á cada barra, por medio de una balanza de resorte, un empuje tal, que conserve la aguja de cada balanza siempre en la misma marca. Como, por ejemplo, en el n.º 2 en las dos balanzas. Tenemos así iguales fuerzas obrando sobre desiguales masas †. En este caso la aceleración comunicada á la masa *a* es doble de la comunicada á la A; pues cuando las **fuerzas son iguales, las aceleraciones están en razón inversa de las masas.**

En otras palabras, en un segundo (ó en cualquier otro tiempo dado), la pequeña barra de hierro *a* adquirirá doble aumento de velocidad que el que adquirirá A (de doble longitud), de modo que, si las dos barras parten al mismo tiempo de

---

(*) Hablamos aquí de la fuerza de la gravedad ejercida en un lugar dado, como fuerza constante, porque esto basta para todos los fines prácticos. Hablando en un sentido estricto, aumenta muy poco á medida que la piedra se aproxima á la tierra.

† La masa de un cuerpo es la cantidad de materia que contiene.

su estado de reposo, la más pequeña, *a*, tendrá, al fin de cualquier tiempo dado, dos veces la velocidad de A, que tiene doble masa.

(b) Ahora, supongamos que las dos masas A y *a* sean iguales, pero hagamos que la *fuerza ejercida* sobre *a* sea doble de la que se ejerce sobre A; entonces la aceleración de *a* será (como antes) doble de la de A, porque **cuando las masas son iguales, las aceleraciones están en proporción de las fuerzas.**

(c) De esta manera llegamos á deducir el principio de que, en cualquier caso, **la aceleración es directamente proporciona lá la fuerza é invoersamente proporcional á las masas.**

(d) Así pues, si hacemos las dos fuerzas proporcionales á las dos masas, las aceleraciones serán iguales, ó **para una aceleración dada las fuerzas están en razón directa de las masas.**

(e) Por consiguiente, mayor fuerza se requiere para comunicar una velocidad dada á un cuerpo dado, en un tiempo corto, que para comunicarle la misma velocidad en mayor tiempo. Por ejemplo, los eslabones de unión de adelante en una larga serie de vagones se harían pedazos instantáneamente bajo una tracción suficiente á darle al tren en dos segundos una velocidad de 20 millas (32 km) por hora, suponiendo que existiera una locomotora suficientemente poderosa para ello. En muchos casos semejantes tenemos que contentarnos con una aceleración lenta en lugar de una rápida.

Una cuerda puede sostener con seguridad un peso de una libra suspendido de nuestra mano; pero si queremos comunicarle al peso una gran velocidad ascendente en un *tiempo muy corto*, podemos hacerlo, pero ejerciendo sobre él una gran fuerza ó, en otras palabras, tirando violentamente de la cuerda hacia arriba. Si la cuerda no tiene suficiente resistencia á la tensión para transmitir esta fuerza de nuestra mano al peso, se reventará. Podríamos con más seguridad darle al peso la velocidad deseada empleando una fuerza *menor* durante un *tiempo mayor*.

(f) Cuando una piedra cae, *la fuerza* que atrae la tierra hacia arriba es (como se ha dicho anteriormente) igual á la que atrae la piedra hacia abajo; pero la masa de la tierra es tantísimas veces mayor que la de la piedra, que su movimiento es totalmente imperceptible para nosotros, y lo mismo sería aun cuando no estuviera equilibrada por otros movimientos en otras direcciones y en otras partes de la tierra. Por consiguiente, tenemos razón, dada la insignificancia del fenómeno, aunque *no de un modo absoluto*, cuando decimos que la tierra permanece *en reposo* durante la caída de la piedra.

(g) Pero, en el caso de las dos bolas de billar (artículo 5*c*), podremos ver claramente el resultado de la acción de la fuerza sobre cada uno de los dos cuerpos, puesto que la segunda bola, B, que estaba en reposo se mueve ahora hacia adelante, mientras que la velocidad de avance de la primera, A, se ha disminuído ó destruído, apareciendo su movimiento de retroceso, como un *retardo* de su movimiento de avance; y (como la misma fuerza obra sobre ambas bolas) tenemos

$$\frac{\text{masa de A}}{\text{masa de B}} :: \frac{\text{la aceleración de B}}{\text{la aceleración } \textit{negativa} \text{ de A}}$$

ó (puesto que la fuerza obra durante el mismo tiempo sobre ambas bolas),

$$\frac{\text{masa de A}}{\text{masa de B}} :: \frac{\text{velocidad de avance de B}}{\text{pérdida de velocidad de A.}}$$

(h) *Observación.* Un hombre no puede *levantar* un peso de 20 toneladas; pero si se coloca éste sobre buenos rodillos, puede *moverlo* horizontalmente, como vemos en los puentes levadizos, placas giratorias, etc.; y si el frotamiento y la resistencia del aire pudieran suprimirse, lo podría mover con un soplo de la respiración y continuaría moviéndose después que el soplo hubiera cesado de obrar sobre él. Se movería, sin embargo, muy lentamente porque la fuerza muy débil de la simple respiración tendría que repartirse entre 20 toneladas de materia. Se puede mover si se coloca en un envase conveniente en el agua ó si se suspende de una larga cuerda. Una locomotora poderosa que pueda mover 2000 toneladas no podría suspender verticalmente 10.

Si imaginamos dos cuerpos, cada uno tan grande y pesado como la tierra, precisamente equilibrados en una balanza sin frotamiento, un simple grano de arena agregado á cualquiera de los dos platillos de la balanza les comunicaría movimiento á ambos cuerpos.

**Art. 10** (a). La fuerza constante de la gravedad es una fuerza aceleratriz uniforme, cuando obra sobre un cuerpo que cae librem ente, porque comunica á la velocidad un aumento uniforme, á razón de .0981 m durante cada

centésima parte de un segundo, ó de 9.81 m por segundo, durante cada segundo. También cuando obra sobre un cuerpo que se mueve hacia abajo en un plano inclinado; sin embargo de que, en este caso, el aumento no es tan rápido, porque es causado por sólo una parte de la gravedad, mientras que otra parte comprime el cuerpo contra el plano y otra tercera parte se emplea en vencer el frotamiento. Es una fuerza uniformemente retardada, cuando obra sobre un cuerpo lanzado hacia arriba verticalmente; porque sea cual fuere la velocidad del cuerpo, al lanzarlo hacia arriba disminuirá á razón de .098 m en cada centésima parte de un segundo, durante su elevación, ó 9.81 m por segundo durante cada segundo entero. Por lo menos, tal sería el caso si no fuera por las variadas resistencias que va presentando el aire en las diferentes velocidades que va adquiriendo el cuerpo. La gravedad es una fuerza uniforme de compresión ó de tensión, cuando hace que un cuerpo en reposo comprima á otro cuerpo ó cuando hace que tire de una cuerda á la cual está suspendido. Las expresiones anteriores, como cantidad de movimiento (momentum), compresión, tensión, impulso, empuje, levantamiento, trabajo, etc., no indican diferentes *clases* de fuerzas, sino simplemente diferentes clases de *efectos*, producidos por la gran causa principal llamada fuerza.

(**b**) Los 9.81 m por segundo mencionados se llaman **aceleración de la gravedad**, y está convencionalmente representada, por los escritores científicos, por medio de la letra **g**; ó, hablando más correctamente, no siendo la aceleración precisamente la misma en todos los puntos de la tierra, $g$ indica la aceleración por segundo, sea cual fuere el lugar de que se trate.

**Art. 11 (a). Relación entre la fuerza y la masa.** La masa de un cuerpo es la cantidad de materia que éste contiene. *Un* metro cúbico de agua tiene **doble** masa que *medio* metro cúbico; pero tiene *menos* masa que un metro cúbico de hierro. Así, pues, el *tamaño* de un cuerpo es la medida de la masa entre cuerpos de la *misma* substancia, pero no de la de cuerpos de *diferentes* substancias.

(**b**) Cuando se han dejado caer cuerpos libremente en el vacío, en un lugar dado, se ha visto que adquieren iguales velocidades en cualquier tiempo dado, sea cual fuere la substancia de que estén compuestos. Por esto sabemos (art. 9 *d*) que la fuerza que los hace descender, es decir, sus respectivos *pesos* en aquel lugar, deben ser proporcionales á sus *masas*.

Así, *en cualquier lugar dado*, el *peso* de un cuerpo es la medida exacta de su *masa*. Pero el *peso* de un cuerpo dado *cambia* cuando se traslada el cuerpo de una altura sobre el mar á otra, ó de una latitud á otra; mientras que la *masa* de un cuerpo permanece *la misma* en todos los lugares. Así, un pedazo de hierro que pesa un kilogramo al nivel del mar, pesará *menos* de un kilogramo pesándolo, por medio de una balanza de resorte, sobre una montaña cercana; porque la atracción entre la tierra y una masa dada, disminuye cuando la última se aleja del centro de la tierra. O, si el pedazo de hierro pesa un kilogramo cerca del polo norte ó del polo sur, pesará por la misma razón *menos* de un kilogramo en una balanza de resorte, si se pesa más próximo al ecuador y á la misma altura sobre el nivel del mar.

La diferencia del peso de un cuerpo en distintas localidades, es tan pequeña que no hay para qué tomarla en cuenta en los problemas de mecánica práctica *; pero la exactitud científica requiere una medida de la masa que dé la misma cantidad de materia para el contenido de un cuerpo dado, dondequiera que esté, y como el peso es un medio muy *conveniente* para llegar á la cantidad de materia que contiene un cuerpo, es de desearse que pudiéramos expresar la masa por los pesos. Ahora, cuando un cuerpo dado se traslada á un nivel más alto ó á una latitud más baja, su pérdida de peso es simplemente una disminución en la *fuerza* con la cual la gravedad lo atrae hacia abajo, y esta misma disminución produce también una disminución en la *velocidad* que el cuerpo adquiere al caer durante cualquier tiempo dado. El cambio de su velocidad, según el art. 9 (*b*), es necesariamente proporcional al cambio de su peso. Por lo tanto, si el peso de un cuerpo en cualquier lugar se divide por la velocidad en un segundo en el mismo lugar (llamada $g$ ó *aceleración de la gravedad* para aquel lugar), el *cociente* será el mismo en todos los lugares, y, por consiguiente, sirve como medida invariable de la masa.

(**c**) De común acuerdo, la *unidad de masa* en mecánica se dice que es la cantidad de materia á la cual una *unidad* de fuerza le comunica una unidad de ace-

* La mayor discrepancia que puede ocurrir en varias alturas y latitudes, por la adopción del peso como medida de cantidad, no excederá de 1 en 300; ó, en las circunstancias ordinarias, 1 en 1000.

leración. Esta unidad de aceleración, en paises donde se usan las medidas inglesas, es un pie por segundo, cada segundo. Resta entonces acordar las unidades de *fuerza* y de *masa*. Dos métodos (uno viejo y otro nuevo) están en uso para hacer esto. Nos referiremos á ellos llamándolos métodos A y B respectivamente.

(d) **En el método A**, usado todavía generalmente en cuestiones de *estática*, la **unidad de fuerza** está determinada por la fuerza que es igual al *peso de una libra* (un kilogramo en el sistema métrico) en un lugar determinado; esto es, la fuerza con la cual la tierra atrae, en aquel lugar, cierta medida de platino llamada una libra; y la unidad de *masa*, como se ha dicho en (c), la masa á la cual esta fuerza de una libra le comunica en un segundo una velocidad de un pie por segundo. Ahora bien, la fuerza de un kg de atracción de la tierra sobre una masa de un kg comunicará en un segundo á aquella masa una velocidad $=g$ ó digamos 10 metros; y como, art. 9 (*a*), para una fuerza dada las masas están en razón inversa de las velocidades comunicadas en un tiempo dado, para comunicarle en un segundo una velocidad de solo *un metro* por segundo (en lugar de $g$, ó como 10 m) el kg unidad de fuerza tendría que obrar sobre una masa $g$ veces mayor (10 veces) de la que pesa un kg.

Esto se podria demostrar con una máquina de Attwood, art. 16 (c), haciendo á cada uno de los dos pesos iguales á cuatro y medio kg y el peso adicional $=1$ kg.

Según el método A, por consiguiente, la unidad de masa es $g$ veces la masa de la pieza modelo, de metal, llamada un kg; es decir: un cuerpo que contiene una unidad de masa tal, pesa $g$ kg, ó por el **método A**,

$$\text{el peso de cualquier cuerpo dado, en kg} = g \times \text{la } \textit{masa} \text{ del cuerpo en unidades de masa.}$$

ó

$$\text{a } \textit{masa} \text{ del cuerpo en unidades de masa} = \frac{\text{el peso del cuerpo en kg}}{g}$$

Por ejemplo (*N. del T.* — Tomando á $g$ por 10, en lugar de su justo valor, para facilitar los ejemplos análogos á los que da el autor con las libras):

| En un cuerpo que pesa | La masa es como |
|---|---|
| ½ kg. | $\frac{1}{20}$ unidades de masa |
| 1 — | $\frac{1}{10}$ — |
| 2 — | $\frac{1}{5}$ — |
| 10 — | 1 — |
| 20 — | 2 — |

(e) **Por el método B**, la *masa* del kg modelo de platino se toma como la **unidad de masa** y se llama un **kilogramo**, y la fuerza que le comunica en un segundo una velocidad de un metro por segundo se toma como la unidad de **fuerza**. Esta unidad de fuerza se llama un **kilográmetro**.

Por consiguiente, **por el método B**,

$$\text{la masa de cualquier cuerpo dado en kg} = \frac{\text{el peso del cuerpo respectivamente en kg}}{g \text{ (en metros)}}$$

y

$$\text{el } \textit{peso} \text{ de un cuerpo} = g \times \text{la } \textit{masa} \text{ del cuerpo.}$$

(f) En el sistema **C. G. S.** (**centímetro-gramo-segundo**) una fuerza de una **dina**, obrando durante **un segundo**, sobre una masa de **1 gramo**, le comunica á ésta una velocidad de **1 centímetro por segundo**. Véase también el art. 17 (*b*).

**Art. 12** (a). El producto, fuerza × tiempo, se llama **impulso**. El producto masa × velocidad (cantidad de movimiento) ó **momentum** (texto inglés).

De acuerdo con **la segunda ley de Newton**,

$$\left.\begin{matrix}\text{Fuerza} \times \text{tiempo} = \text{masa} \times \text{velocidad} \\ \text{ó impulso} = \text{momentum}\end{matrix}\right\} \text{ ó bien, } ft = mv \ldots\ldots \quad (1)$$

$$\text{Fuerza} = \frac{\text{impulso}}{\text{tiempo}} = \frac{\text{masa} \times \text{vel}}{\text{tiempo}} = \frac{\text{momentum}}{\text{tiempo}}; \quad \text{ó bien } f = \frac{mv}{t} \ldots\ldots \quad (2)$$

$$\text{Tiempo} = \frac{\text{impulso}}{\text{fuerza}} = \frac{\text{masa} \times \text{vel}}{\text{fuerza}} = \frac{\text{momentum}}{\text{fuerza}}; \quad \text{ó bien } t = \frac{mv}{f} \ldots\ldots \quad (3)$$

$$\text{Masa} = \frac{\text{momentum}}{\text{velocidad}} = \frac{\text{fuerza} \times \text{tiempo}}{\text{velocidad}} = \frac{\text{impulso}}{\text{velocidad}}; \text{ ó bien } m = \frac{ft}{v} \ldots \quad (4)$$

$$\text{Velocidad} = \frac{\text{momentum}}{\text{masa}} = \frac{\text{fuerza} \times \text{tiempo}}{\text{masa}} = \frac{\text{impulso}}{\text{masa}}; \quad \text{ó bien } v = \frac{ft}{m} \ldots \quad (5)$$

(*Observación del T.* — Para la mejor comprensión de esta materia, en el sistema métrico, nos parece preferible reemplazar los últimos renglones de este párrafo (*f*) con la siguiente exposición tomada de un tratado elemental de física.)

**Unidades C. G. S. de masa y fuerza.** En el sistema C. G. S., la unidad de masa es una unidad fundamental, denominada *gramo* (masa), que es la *milésima* parte de la masa del kilogramo (masa), tipo que se guarda en los Archivos internacionales de Sèvres.

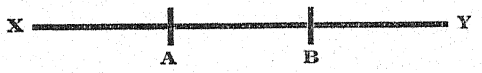
Este último debería representar la masa del decímetro cúbico de agua destilada, á la temperatura de 4º centígrados, pero difiere de ella una cierta cantidad muy pequeña, pero apreciable. Las medidas más precisas asignan, en efecto, al decímetro de agua pura á los 4º el valor de 1,000.013 gr. C. G. S., y, por consiguiente, al centímetro cúbico de agua pura á 4ºC, la masa 1.000 013 gr. C. G. S.

La relación $F = mj$ impone la elección de la unidad de fuerza. Si, en efecto, se hace $m = 1$ y $j = 1$, F debe ser también igual á 1. La unidad de fuerza es, pues, *la fuerza que actuando sobre la unidad de masa le imprime la unidad de aceleración.*

El peso de un gramo, producto de su masa igual á 1 por la aceleración 980.96 (en París) de la caída de los cuerpos, vale, pues, 980.86 *dinas* y la *dina* equivale, por tanto, *aproximadamente al peso de un miligramo.*

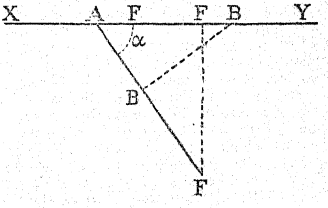
Es, pues, esta unidad una fuerza muy variable. Para expresar fuerzas un poco grandes se emplea frecuentemente una unidad secundaria, *la megadina*, que vale un millón de dinas (1 kilogramo aproximadamente).

**Trabajo mecánico de una fuerza constante en magnitud y en dirección. 1.º Caso en que el punto de aplicación se traslada en la dirección de la fuerza.** Se llama *trabajo de la fuerza* (para conducir su punto de aplicación desde A hasta B) *el producto del espacio*



AB = *e* (en unidades de longitud) *por la intensidad* F *de la fuerza* (en unidades de fuerza). Se tiene, pues, T = *Fe*.

Si la fuerza actúa en el sentido de la traslación XY, se dice que es *moviente* ó *motora* y que su trabajo es positivo; si la fuerza actúa en sentido contrario del camino recorrido, se dice que es *resistente* y que su trabajo es negativo: T = — (*Fe*).

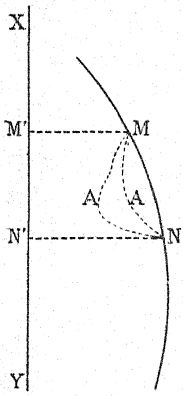


**2.º Caso de un traslado rectilíneo que no está en la dirección de la fuerza. El trabajo es entonces el producto de la fuerza por el camino recorrido, y por el coseno del ángulo de las dos direcciones**: $T = Fe \cos \alpha$. El trabajo es positivo ó negativo según que cos α es positivo ó negativo, es decir, según que α es un ángulo agudo ú obtuso. En el caso en que α es agudo, la proyección de la fuerza sobre la dirección del camino recorrido está dirigida en el mismo sentido que éste; se

puede decir que la fuerza proyectada es *motora;* lo contrario sucede en el caso en que $\alpha$ es obtuso; la proyección de la fuerza es *resistente.*

*Observación.* Se puede también considerar el producto $e \cos \alpha$, como la proyección AB' del camino sobre la dirección de la fuerza é incluir este caso en el precedente.

**3.° El punto de aplicación de la fuerza recorre una trayectoria curvilínea. El trabajo es entonces el producto de la fuerza por la proyección del arco de trayectoria MN ó MA₁N sobre la dirección constante XY de la fuerza:** $T = F \times M'N' = F \times MA_1N$.



**La intensidad (ó aceleración) de la gravedad,** ó la aceleración producida, en cualquier masa por su propio peso, se llama $g$, y á nivel del mar es como de 9.81 m (32.2 pies) por segundo en cada segundo. Véase el capítulo « Gravedad, caída de los cuerpos », pág. 364.

**Art. 13 (a).** Una fuerza se mide comúnmente por el valor de otra fuerza que ella puede destruir. Así, una balanza de resorte da por su escala en el resorte la intensidad de la tensión que justamente equilibra el peso de la masa suspendida. Así **las fuerzas se expresan convenientemente por pesos.**

**Una fuerza puede ser constante,** como la de la gravedad entre la tierra y una piedra colocada sobre ella. **Puede variar regularmente,** como la presión del aire comprimido por un émbolo que se mueva con una velocidad constante, **ó variar irregularmente,** como cuando el movimiento del émbolo dicho es irregular. Trataremos sólo de las fuerzas, suponiéndolas constantes.

(*N. del T.*— Se toma, en la práctica, como unidad de masa, la masa de un cuerpo que pese *un kilogramo* en el ecuador á nivel del mar y como unidad de velocidad la unidad de longitud ó sea un metro en la unidad de tiempo, un segundo. Tendremos que la unidad de fuerza será la que haga mover una masa de *un kilogramo* á *un metro* en un segundo; ésta se llama *kilogramo-metro* ó, abreviando, *kilogrametro* y se deduce también de la fórmula (1): en efecto, $f \times t = m \times v$; poniendo en lugar de $t$, $m$, $v$, sus valores 1 seg, 1 kilogramo, 1 metro, viene $f \times 1 = 1 \times 1$; de donde $f = 1$. La *unidad de fuerza*, ó la unidad de la *cantidad de movimiento*, ó la unidad de *momentum*, como la llama el autor, es en el sistema métrico *un kilogrametro por segundo.*)

**Art. 14 (a). Densidad.** Las *densidades* de las substancias son proporcionales á las *masas* contenidas en un *volumen* dado, como una pulgada ó un centímetro cúbico, ó en *razón inversa* del *volumen* requerido para contener una *masa* dada. Y como los pesos en un lugar dado son proporcionales á las masas, las densidades son proporcionales á los pesos por unidad de volumen (pesos específicos) de las materias. Así, un cuerpo que pesa á razón de 10 kilogramos el decímetro cúbico, tiene una densidad doble que uno que pesa solamente á razón de 5 kilogramos el decímetro cúbico en el mismo lugar.

**Art. 15 (a). Inercia.** Se llama inercia la incapacidad de la materia para ponerse en movimiento por sí sola, ó para modificar el grado ó dirección de su movimento. Cuando decimos que cierto cuerpo tiene doble inercia que otro, significamos con esto que se requiere *doble fuerza* para darle igual aceleración; y como toda fuerza, art. 5 (f), obra del mismo modo en ambas direcciones, experimentamos una *reacción* dos veces mayor (llamada « resistencia ») con el cuerpo más grande que con el más pequeño. La « inercia » de un cuerpo es, por consiguiente, una medida de la *fuerza* que se requiere para producir en él una aceleración dada, ó, lo que es lo mismo, es una medida de la *masa* del cuerpo. Por lo tanto, podemos considerar a « inercia » y la *masa* como idénticas.

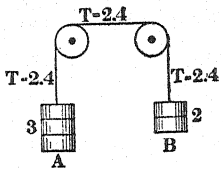
**(b)** Lo que se llama « resistencia de inercia » de un cuerpo, es simplemente la reacción (esto es, una de las dos acciones iguales y opuestas) de cualquiera fuerza que apliquemos al cuerpo. De aquí que su intensidad depende no solamente de la masa del cuerpo, sino también de la cantidad de aceleración que le comuniquemos. Por consiguiente, no podemos decir, por medio de la masa ó del peso solo de un cuerpo, cuál sea su « resistencia » en un caso dado.

**Art. 16 (a). Fuerzas en opuestas direcciones.** Cuando dos fuerzas iguales y opuestas obran sobre un cuerpo á un mismo tiempo y en la misma línea rectas decimos que sus tendencias mutuas á mover el cuerpo se destruyen y aquél permanece en reposo. Si dos fuerzas *desiguales* obran opuestamente, la fuerza ám-

pequeña y una parte de la mayor igual á aquélla se contrarían y destruyen mutuamente; pero lo que queda de la fuerza mayor, obra como una fuerza á la cual no se opone resistencia y mueve el cuerpo en su dirección propia, como lo haría si fuera la única fuerza que obrara sobre él.

Así, cuando en la práctica diaria movemos los cuerpos, no sólo tenemos que aplicar fuerzas para vencer la « resistencia de la inercia », sino también otras fuerzas que se nos oponen, como la fricción, la resistencia del aire y, muchas veces, parte ó la totalidad del *peso* del cuerpo. Cuando en lo sucesivo hablemos de « resistencias » nos referiremos siempre á estas fuerzas citadas sin incluir la « resistencia de la inercia ».

(b) Si separados los dos cuerpos A y B, de 3 y 2 kg respectivamente, deben caer con igual aceleración $g$, cada unidad de masa, $\frac{w}{g}$, estará solicitada por su solo peso. Conectados, como lo están, A se moverá hacia abajo y B hacia arriba, con una aceleración = solamente á $\frac{g}{3+2} = \frac{g}{5}$; ahora bien, una fuerza no equilibrada de sólo $3 - 2 = 1$ kg debe comunicarle aceleración á una masa de $\frac{3+2}{g} = \frac{5}{g}$. Pero, para darle á una masa B, de $\frac{2}{g}$, una aceleración de $\frac{g}{5}$, se requiere una fuerza de $\frac{2}{g} \cdot \frac{g}{5} = \frac{2}{5}$ kg $= .4$ kg. Esta, más 2 kg (requeridos para equilibrar el peso de B), es la tensión 2.4 kg que se ejerce por la cuerda. Ejercida en A, esta tensión equi-



libra 2.4 de los 3 kg que pesa A. El residuo ($3 - 2.4 = .6$ kg), obrando hacia abajo sobre la masa $\frac{3}{g}$ de A, le comunica la requerida aceleración de $\frac{g}{5}$; pues aquí $\frac{\text{fuerza}}{\text{masa}} = .6 \div \frac{3}{g} = \frac{.6g}{3} = .2g = \frac{g}{5}$. O bien, considérese la tensión total, 2.4 kg en la cuerda, en A, obrando sobre A y comunicándole una *aceleración hacia arriba, negativa* de $2.4 \div \frac{3}{g} = .8g$; la que deducida de $g$ (la aceleración que A tendría por sí), queda :

$$\text{Aceleración} = g - .8g = .2g = \frac{g}{5}.$$

Sea W = el peso de A;
$w$ = el peso de B;
F = fuerza que queda para comunicar aceleración = $W - w$;
M = masas combinadas de los dos cuerpos = $\frac{W+w}{g}$;
$m$ = masa de B = $\frac{w}{g}$;
$a$ = aceleración;
T = tensión en la cuerda.

Entonces : $$a = \frac{F}{M} = (W - w) \div \frac{W+w}{g} = \frac{g\,(W - w)}{W + w}$$

$$T = w + ma = w + \frac{w}{g}\,a = w + \frac{w}{g} \cdot \frac{g\,(W - w)}{W + w} = w\left(1 + \frac{W - w}{W + w}\right).$$

(c) Una **máquina de Atwood** consiste esencialmente en una polea, una cuerda flexible que pasa por sobre la polea, dos pesos iguales (suspendido cada

uno á un extremo de la cuerda) y un tercer peso, generalmente mucho más liviano que los otros dos. Los dos pesos iguales se equilibran por medio de la polea y la cuerda. El tercero se coloca sobre uno de los otros dos pesos. La fuerza de la gravedad obrando sobre el tercer peso, pone entonces las masas de los tres pesos en movimiento, á una pequeña pero constante velocidad creciente. Para lograr esto se debe vencer también el frotamiento de la polea con la cuerda, y la rigidez de la última; pero como la cuerda se hace tan delgada como sea posible, no se toman en cuenta. Se usa la máquina para estudiar las aceleraciones comunicadas á la materia inerte por medio de fuerzas no equilibradas, y constituye un excelente ejemplo de los dos distintos efectos que tiene que realizar generalmente una fuerza motriz, á saber : 1.º equilibrar las resistencias, y 2.º comunicar la aceleración.

(**d**) En el caso de una **locomotora que arrastre un tren sobre una línea horizontal**, el frotamiento y la resistencia del aire son las únicas resistencias que hay que vencer. pues el peso del tren no opone resistencia en este caso. Si la fuerza del vapor no es *más* que suficiente para equilibrar las resistencias, no puede mover el tren. Si excede á las resistencias, el exceso, por pequeño que sea, le comunica movimiento á la masa inerte del tren. Si en cualquier momento durante el movimiento del tren, la fuerza del vapor se hace *precisamente igual á las resistencias* (sea por un aumento de las últimas y por disminución de la fuerza), el tren continuará moviéndose con una velocidad *uniforme* igual á la que tenía en el momento en que la fuerza y resistencias estaban compensadas, y si se pudiese conservar siempre igual, se seguirá moviendo indefinidamente así.

Pero mientras el excesc de presión de vapor sobre las resistencias continúe abrando, se aumentará la velocidad á cada instante, porque durante cada uno de dichos instantes el exceso de fuerza agrega una pequeña velocidad á la que ya existe.

En un ferrocarril á nivel sea : (*N. del T.* — En este ejemplo hemos cambiado el cálculo, hecho en sistema inglés, por el métrico.)

P=la fuerza total de tracción de la locomotora=13 tons;
W=peso de la locomotora=50 tons;
V=peso del tren=336 tons;
R=resistencia de la locomotora (incluyendo fricciones interiores, etc.)=3 tons;
$r$=resistencia del tren=1 ton;
F=fuerza disponible para producir aceleración=P—R—$r$=9 tons;
M=masa de la máquina y del tren $= \frac{W+w}{g} = \frac{50+336}{g} = \frac{386}{9.81} = 39.35$;
$m$=masa del tren= $\frac{336}{9.81} = 34.25$;
$a$=aceleración;
T=tensión en la barra de enganche.

Entonces la aceleración $= a = \frac{F}{M} = \frac{9}{39.35} = .228$ m por segundo en cada segundo.

La tensión T, en la barra de enganche=á la resistencia del tren+la fuerza que produce la aceleración $a$, ó bien T=$r$+$ma$=1+34.25×.228=8.81 tons.

Esta tensión T, tirando de la locomotora hacia atrás, produce allí una *retardación ó aceleración negativa* de $\frac{T}{\text{masa de la locomotora}} = \frac{8.81\,g}{50} = 1.73$ mts por segundo, en cada segundo, y esto reduce, en dicha cantidad, la aceleración que la locomotura tendría y que hubiera sido $= \frac{(P—R)g}{50} = \frac{10 \times 9.81}{50} = 1$ m 96. Esta de 1 m 96—1.73=.23 mts por seg, en cada segundo=á la aceleración del tren

(**e**) Si la fuerza de tracción de una locomotora excede á las resistencias debidas á la fricción, al aire, á las pendientes, la velocidad se acelerará; pero entonces se hace más dificultoso mantener el exceso de fuerza, porque los émbolos tienen que moverse más rápidamente en los cilindros y la caldera no suple el vapor con suficiente rapidez para mantener la presión original en el cilindro; fuera de que algunas resistencias crecen con la velocidad. Así se llega á una velocidad en la cual, aunque la máquina desarrolle su fuerza máxima, no puede hacer más que equilibrar las resistencias. El tren se mueve entonces con una velocidad uniforme igual á la que tenía cuando se llegó á tales condiciones.

Cuando se hace necesario detenerse en alguna estación á cierta distancia, se cierra el vapor á fin de que su fuerza no equilibre por más tiempo las resistencias y además se aumenta el número de estas resistencias agregándoles la fricción de los frenos. Las resistencias así aumentadas son las únicas fuerzas que obran sobre el tren, y su aceleración es *negativa* ó de *retardo*. Por consiguiente, el tren se mueve más y más despacio y tiene al fin que pararse.

(*f*) **Advertencia.** Cuando dos fuerzas opuestas se hallan en equilibrio, un aumento hecho á una cualquiera de ellas, no siempre rompe su estado de equilibrio, pues en muchos casos *la otra fuerza aumenta igualmente* hasta cierto punto. Por ejemplo, cuando tratamos de levantar un peso W, su *resistencia* hacia abajo R, permance constantemente igual al esfuerzo paulatino hacia arriba P; sin embargo, P puede variar hasta que *exceda* á W, en cambio R no puede *exceder* nunca á W, pero puede ser mucho menos que él. Efectivamente, cuando se deja de empujar, R cesa á pesar de que W (la atracción entre la tierra y el peso) permanece la misma siempre. Tales variaciones de las fuerzas resistentes para hacer frente á las variaciones que ocurran, tienen efecto en todos aquellos casos innumerables en que las construcciones soportan pesos variables entre los límites de sus resistencias extremas.

**Art. 17 (a). Trabajo.** Cuando la fuerza mueve á un cuerpo * se dice que hace un trabajo. La totalidad del trabajo hecho por la fuerza, al mover el cuerpo á una distancia cualquiera, se mide multiplicando la *fuerza* por la distancia; ó *Trabajo* = = fuerza × distancia. Si la *fuerza* está tomada en *libras* y la *distancia* en *pies*, el producto (ó el trabajo hecho) está dado en *pies-libras* y (en *kilográmetros* si se toman kilogramos y metros respectivamente)†.

| Así, si una fuerza de | mueve un cuerpo á | su trabajo es de |
|---|---|---|
| 1 kilogramo | 10,000 metros | 10,000 kilográmetros |
| 100 kilogramos | 100 — | 10,000 — |
| 10,000 — | 1 metro | 10,000 — |

En cualquier caso, si la fuerza es de F libra ó F′ kilogramos, el trabajo total hecho al mover un cuerpo á lo largo de S pies ó S′ metros es F × S pies libras ó F′ × S′ kilográmetros.

(**b**) Con medidas inglesas la unidad ordinaria de **trabajo** es el **pie-libra**. **La unidad métrica de trabajo** es el **kilogramo-metro** ó, abreviando, **kilográmetro**. Véanse las tablas de conversión pág. 247.

**En el sistema C. G. S.** (Art. 11 *f*), 1 dina obrando en 1 centímetro de longitud produce **1 erg (una dina-centímetro)** de trabajo. 1 joule (pág. 247) = 10,000,000 ergs = .7373 pie-libra = .1019 kilográmetro. 1 kilográmetro = 9,812 joule.

(**c**) En la mayor parte de los casos, una porción por lo menos del **trabajo** hecho por una fuerza, **se emplea en vencer las resistencias.** Así, cuando una locomotora comienza á mover un tren, una parte de su fuerza trabaja contra los frotamientos ó para vencer una subida, mientras que la restante, obrando como fuerza *no* equilibrada sobre la masa inerte del tren, aumenta su velocidad.

Un esfuerzo hacia arriba de un kg no levantará un peso de un kg, sino que simplemente equilibrará la fuerza hacia abajo de la gravedad. Si aumentamos el impulso hacia arriba en un gramo, este gramo así agregado, y como fuerza no equilibrada, le comunicará movimiento á la masa y aumentará su velocidad hacia arriba todo el tiempo que continúe obrando.

Si reducimos ahora el empuje hacia arriba á un kg haciéndolo así exactamente igual á la fuerza de la gravedad hacia abajo, el cuerpo seguirá moviéndose hacia arriba con una velocidad uniforme; pero, si reducimos la fuerza hacia arriba á 999 gramos, habrá entonces una fuerza no equilibrada hacia abajo de 1 gramo, obrando sobre el cuerpo, y esta fuerza hacia abajo producirá en el cuerpo una velocidad hacia abajo, una aceleración *negativa*, ó *retardación*, y *destruirá* la velocidad hacia arriba en el mismo tiempo que necesitó el exceso *hacia arriba* de 1 gramo para *producirla*.

Durante cualquie tiempo, mientras los 1,001 gramos de « fuerza » ascendente obraban contra los 1,000 gramos de « resistencias » descendente, el producto de la fuerza total ascendente × la distancia debe ser *mayor* que el de la *resistencia* × la

---

* Un hombre que esté parado, sin movimiento, no se le considera haciendo ningún trabajo; lo mismo se dice de un poste ó de una cuerda cuando sostienen una carga pesada; aunque aquél esté soportando una fuerte carga opresiva ó sosteniendo una carretilla de mano con toda su fuerza, porque ésta no está moviendo nada en ningún caso.

† Este producto no se debe confundir con el de los momentos = fuerza × brazo de palanca.

distancia. El exceso es el trabajo realizado para acelerar la velocidad, en virtud de la cual el cuerpo ha adquirido energía cinemática ó *capacidad para realizar un trabajo al volver al reposo*.

Por otra parte, mientras la velocidad ascendente se *retardaba*, el producto de la fuerza total ascendente × la distancia era *menor* que el de las *resistencias* × la distancia, siendo la diferencia de trabajo hecho por la energía cinemática contra la resistencia de la gravedad.

En la práctica, el término **trabajo** se emplea generalmente de modo restringido á aquella *parte* del trabajo que una fuerza ejecuta para equilibrar las *resistencias* que obran contra ella; en otras palabras, al trabajo ejecutado por una cantidad de fuerza igual á la resistencia.

Con esta restricción tenemos:

Trabajo = *fuerza* × distancia = *resistencia* × distancia.

Así, si la resistencia es un frotamiento de 4 kg vencida en todos los puntos en un distancia de 3 m, ó si es un peso de 4 kg, suspendido á 3 m de altura, entonces el trabajo ejecutado alcanza á 4 × 3 = 12 kilográmetros, suponiendo que las velocidades inicial y final sean iguales.

(d) En casos en **que la velocidad es uniforme**, como en una máquina giratoria sólida, la fuerza es necesariamente igual á la resistencia, y cuando las velocidades al principio y al fin de cualquier trabajo son iguales (como cuando la máquina parte del reposo y vuelve á él otra vez), la fuerza *media* es igual á la resistencia *media*. En dichos casos es claro que, los dos productos, fuerza media × distancia y resistencia media × distancia, son iguales, y tenemos como antes:

Trabajo = *fuerza* × distancia = *resistencia* × distancia.

(f) Al calcular el trabajo ejecutado por una maquinaria, etc., se debe tener en cuenta el gasto de una parte del trabajo en vencer las resistencias. Así, al extraer agua, una parte de la fuerza aplicada se necesita para equilibrar la fricción de las diferentes partes de la bomba, de manera que una fuerza de vapor ó de agua, de 100 kilogramos, que recorra 6 metros por segundo, no puede levantar 100 kilogramos de agua á una altura de 6 metros por segundo. Por tanto, las máquinas en lugar de *ganar fuerzas*, como se cree vulgarmente, en realidad, pierden. Al *poner en movimiento* una máquina, las fuerzas empleadas tienen: 1.° que equilibrar, destruir ú oponerse contra la fuerza resistente del frotamiento y la cohesión de la materia sobre la que obra; y 2.° comunicarle movimiento á las partes de la máquina á las cuales no se oponen resistencias y á las de las masas mismas después de haber vencido las resistencias que ellas presentaban. Pero después que se ha establecido la velocidad deseada, las fuerzas no tienen sino que equilibrar *las resistencias* á fin de que la velocidad continúe uniforme.

(g) La parte del trabajo de una máquina que se consume se llama algunas veces **trabajo perdido ó trabajo perjudicial**, mientras que se llama **trabajo útil** la parte que efectúa, que crea un servicio visible y tangible.

Así, al extraer agua, el trabajo ejecutado para vencer el frotamiento de la bomba y del agua, se dice que se pierde, y se llama perjudicial, mientras que el trabajo útil está representado por el producto del peso del agua salida × altura á la cual se ha obrado. Esta distinción, aunque artificial y de algún modo arbitraria, es á menudo muy conveniente; pero esa parte del trabajo no está realmente perdido, ni mucho menos es « perjudicial », porque no podría extraerse el agua sin vencer antes las resistencias. Un comerciante podría del mismo modo llamar dinero perdido el que gasta en salarios para sus dependientes, etc.

(h) Para una fuerza y *distancia* dadas, **el trabajo ejecutado es independiente del tiempo**, pues el producto de la fuerza × la distancia permanece el mismo; sea cual fuere el tiempo. Pero la distancia en la cual una *fuerza* dada trabaja con una velocidad dada, es por supuesto proporcional al tiempo durante el cual hace el trabajo. Así, para levantar á 10 metros, 50 kilogramos, un hombre debe hacer el mismo trabajo (= 500 kilográmetros), así lo haga en una hora ó en diez; pero si ejerce la *misma fuerza* constantemente, levantará 50 kg á 10 veces más altura en diez horas que en una, y efectuará de este modo diez veces más trabajo. Por tanto, para una fuerza dada, **el trabajo es proporcional al tiempo.**

**Art. 18 (a). Potencia.** La cantidad de cualquier trabajo puede valorarse, evidentemente, sin considerar el *tiempo* requerido para ejecutarlo; pero necesitamos á menudo conocer la *proporción* en la cual el trabajo se ejecuta, esto es, cuánto puede hacerse en cierto tiempo.

La proporción en la cual puede trabajar una máquina, etc., se llama su *potencia*. Así, al escoger una máquina de vapor es importante saber cuánto puede hacer por

*minuto, hora* ó *día.* Por lo tanto, estipulamos que debe ser de tantos *caballos de fuerza;* lo que significa, nada menos, que debe ser capaz de vencer fuerzas de resistencia á razón de tantas veces 4,500 kilográmetros por minuto, cuando tenga una velocidad constante, esto es, cuando fuerza × distancia = resistencia × distancia.

**(b)** El **caballo de fuerza** (33,000 pies-libras por minuto ó 550 pies-libras por segundo) es la **unidad de fuerza** ó **de proporción de trabajo,** comúnmente usada tratándose de máquinas. El **caballo de fuerza métrico** llamado « caballo de vapor » ó (en alemán) « Pferdekraft », es de 75 kilográmetros por segundo = 542.48 pies-libras por segundo = 32,549 pies-libras por minuto = .9863 caballos de fuerza. El caballo de fuerza = 1,0138 « force de cheval ». En mecánica teórica, el **pie-libra por segundo** se usa en las medidas inglesas y el **kilográmetro por segundo** en las medidas métricas.

1 pie-libra por segundo = .13825 kilográmetro por segundo.
1 kilográmetro por segundo = 7.2331 pies-libra por segundo.

**(c)** Hasta el momento en que la velocidad se hace uniforme, la **fuerza y proporción de trabajo** del tren, art. 16 **(d)**, es *variable, acelerándose* gradualmente. Pues en cada segundo vence sus resistencias (y mueve sus puntos de aplicación) *á mayor distancia* que durante el anterior segundo. También después que se suspende la entrada del vapor, la proporción de trabajo es variable, siendo *retartada* gradualmente. Cuando la fuerza del vapor equilibre exactamente las resistencias, la proporción de trabajo es uniforme.

**(d) Potencia = fuerza × velocidad.** Desde luego que la proporción de trabajo es igual al trabajo ejecutado *en un tiempo dado;* podemos encontrarlo dividiendo el trabajo (en pies-libras ó kilográmetros), ejecutado durante cualquier tiempo dado, por el número de segundos contenido en ese tiempo. Así :

$$\text{Potencia} = \text{proporción de trabajo} = \frac{\text{fuerza en kg} \times \text{distancia en metros}}{\text{número de segundos}}.$$

Pero esto es equivalente á :

$$\text{Potencia} = \text{proporción de trabajo} = \text{fuerza en kg} \times \frac{\text{distancia en mets}}{\text{tiempo en segundos}}$$

$$= \text{fuerza en kg} \times \text{velocidad en metros por segundo.}$$

O si nos ocupamos sólo del trabajo de la fuerza que vence *las resistencias,* ó de los casos en que la velocidad es enteramente uniforme, la misma al principio y fin del trabajo :

$$\underset{\text{por segundo}}{\text{Potencia en kilográmetros}} = \underset{\text{de trabajo}}{\text{proporción}} = \underset{\text{kilogramos}}{\text{resistencia en}} \times \underset{\text{por seg.}}{\text{velocidad en metros}}$$

Así pues, si la resistencia es de 100 kg y es vencida en distancias de 10 mets en cada minuto, ó si la resistencia es de 10 kg y es vencida en distancias de 100 mets por minuto, la proporción del trabajo es en ambos casos la misma, á saber: 1,000 kilográmetros por minuto, porque

kg velocidad kg velocidad.
$100 \times 10 = 10 \times 100 = 1{,}000$ kilográmetros por minuto.

**(e)** La misma « potencia » que vence á una resistencia dada, en una distancia dada, en un tiempo dado, vencerá también otra resistencia en cualquiera otra distancia en el mismo tiempo, siempre que la resistencia y la distancia multiplicadas den al misma cantidad que en el primer caso. Así, la fuerza que suspende 50 kgs á 10 mets en un segundo, elevará en un segundo 500 kgs á un metro ó 25 kgs á 20 mets ó 5000 kgs á $^1/_{10}$ de metro. En la práctica, lo que se acostumbra generalmente para vencer las diferentes resistencias son **ruedas dentadas, correas** ó **palancas.**

Por este medio, la máquina, rueda hidráulica, caballo ú otra fuerza motriz ejerciendo una fuerza dada y moviéndose con una velocidad dada, puede vencer pequeñas resistencias rápidamente ó grandes lentamente, según se desee.

**Art. 19 (a). Trabajo que un cuerpo puede efectuar en virtud de su movimiento** ó (lo que es lo mismo) **el trabajo necesario para poner al cuerpo en reposo. Energía cinemática ó fuerza viva.** Como ya se ha dicho, una fuerza igual al peso de cualquier cuerpo, en cualquier lugar, comunicará en un segundo, á la masa del cuerpo, una velocidad = *g;* que en la superficie de la tierra es como de 9.81 metros por segundo. O si se lanza un cuerpo hacia arriba con una velocidad = *g*, su peso lo hará detener en un segundo.

Desde luego que en el último caso las velocidades dadas al principio y al fin del segundo son, respectivamente, $g$ metros por segundo, y cero. La velocidad *media* del cuerpo es $\frac{g}{2}$ metros por segundo. Por tanto, durante el segundo aumentará $\frac{g}{2}$ metros, es decir, como 4.90 metros. En otras palabras, el trabajo que cualquier cuerpo puede ejecutar por haber sido lanzado hacia arriba con una velocidad inicial (velocidad en el momento de partir) de $g$ metros por segundo, es igual al producto de su peso multiplicado por $\frac{g}{2}$ metros; ó

$$\text{trabajo en kgm} = \text{peso} \times \frac{g}{2}\text{; (en kg y en metros, respectivamente).}$$

Nótese que en este caso (desde que la velocidad inicial $v$ es igual á $g$) $\frac{v}{g} = 1$.

Supongamos ahora que el mismo cuerpo es lanzado hacia arriba con una velocidad *doble* de la anterior; esto es, con una velocidad inicial igual á $2g$ ó 19.62 m por segundo. Desde que la gravedad requiere, art. 8 (c), .2 segundos para comunicar ó destruir esta velocdad, el cuerpo se moverá ahora hacia arriba durante 2 segundos ó dos veces mayor *tiempo* que antes. Pero ahora, su *velocidad* media es $g$ ó dos veces mayor que anteriormente. Por tanto, moviéndose por doble tiempo y con doble velocidad, irá *cuatro veces más* lejos venciendo la misma resistencia que antes; es decir, su propio peso.

Así pues, haciendo su velocidad inicial $v = 2g$, esto es, *doblando* su $\frac{v}{g}$, haciéndolo $= 2$ hemos puesto el cuerpo en estado de hacer *cuatro* veces el trabajo que podía hacer cuando su $\frac{v}{g}$ era 1; así es que el trabajo en el segundo caso es igual al producto del trabajo en el primer caso, multiplicado por el *cuadrado* de $\frac{v}{g}$; ó

$$\text{Trabajo} = \text{peso} \times \frac{g}{2} \times \left(\frac{v}{g}\right)^2$$

$$\text{—} = \text{peso} \times \frac{g}{2} \times \frac{v^2}{g^2}$$

$$\text{—} = \text{peso} \times \frac{v^2}{2g}.$$

Y claro es que será el mismo principio para cualquiera *otra* velocidad. Ahora la cantidad total del trabajo que el cuerpo puede ejecutar es independiente de la cantidad de resistencia contra la cual es ejecutado; pues si aumentamos la resistencia disminuimos la distancia, en la misma proporción, de modo que su producto ó la cantidad de trabajo, permanece el mismo. La fórmula anterior puede ser aplicada, por consiguiente, á todos los casos, esto es, la **cantidad total de trabajo**, en pies-libras ó en kilográmetros, que cualquiera cuerpo ejecutará contra cualquiera resistencia (en virtud de su movimiento únicamente), cuando llega al reposo es:

$$\textbf{Trabajo} = \text{peso del cuerpo en movimiento} \times \frac{\text{cuadrado de su velocidad}}{2g}$$

$$= \text{peso de cuerpo en movimiento} \times \text{caída requerida para comunicarle esta velocidad.}$$

$$= \frac{\text{peso del cuerpo en movimiento}}{g} \times \frac{\text{cuadrado de su velocidad}}{2}.$$

En estas ecuaciones, el *peso* es el que el cuerpo tiene en cualquier lugar dado y $g$ es la aceleración debida á la gravedad en ese mismo lugar.

(b) Desde luego que $\frac{\textit{el peso de un cuerpo}}{g} =$ á su masa (art. 11).

$$\textbf{Trabajo} = \text{masa del cuerpo} \times \frac{\text{cuadrado de su velocidad}}{2}.$$

(c) En las ecuaciones anteriores el lado *izquierdo* representa el *trabajo* (ó resistencia vencida á lo largo de una distancia) en cualquier caso dado, mientras que el lado *derecho* representa la **energía cinemática** del cuerpo, por la cual se pone

en estado de ejecutar aquel trabajo. (*N. del T.* — De la misma ecuación se deduce que el trabajo es igual á la mitad de la fuerza viva ($mv^2$).

(d) Como ejemplo de lo anteriormente dicho, tómese un tren que pesa 500,000 kg y moviéndose á razón de 22 mets por segundo; la *energía cinemática* de dicho tren es:

$$\text{energía} = \text{peso} \times \frac{\text{velocidad}^2}{2g};$$

$$500{,}000 \text{ kg} \times \frac{22^2}{19.62} = 12{,}335{,}000 \text{ kilográmetros.}$$

Esto es, si se impide la entrada del vapor el tren ejecutará un trabajo de 12,335,000 kgm para entrar en reposo. Así pues, si la suma de todas la resistencias (de frotamiento, aire, declive curvas, etc.) permanecen constantemente = 5,000 kg * el tren caminará

$$\frac{12{,}335{,}000 \text{ kgm}}{5{,}000 \text{ kg}} = 2{,}467 \text{ metros.}$$

(e) Vemos así que la cantidad total de trabajo que un cuerpo puede ejecutar en virtud de su movimiento solo y sin el auxilio de fuerzas extrañas, es proporcional al peso del cuerpo y al *cuadrado* de su velocidad cuando comienza á ejecutar el trabajo. Por ejemplo, supongamos que un tren en el momento en que se suprime la entrada del vapor, tiene una velocidad de 10 kilómetros por hora, y que la energía cinemática que le da la velocidad arrastre por sí el tren oponiéndose á las resistencias del camino, etc., hasta una distancia de un cuarto de kilómetro antes de detenerse. Sentado esto, cuando se suspenda el vapor moviéndose el tren á 5,20, 30 ó 40 kilómetros por hora (esto es, con ½,2, 3 ó 4 veces 10 kilómetros por hora), el tren hará $^1/_{16}$, 1, 2$^1/_4$ ó 4 kilómetros (es decir, $^1/_4$, 4, 9 ó 16 veces $^1/_4$ de kilómetro) antes de detenerse. Aquí se supone que la resistencia es uniforme.

Pero la relación del trabajo ejecutado es simplemente proporcional á la resistencia y á la *velocidad* (art. 18 (*d*)). Por tanto, la locomotora cuyo vapor se intercepta á 20, 30 ó 40 kilómetros por hora, no requerirá para correr los 4, 9 ó 16 cuartos de kilómetro sino 2, 3 ó 4 veces tantos segundos cuantos necesitaba á razón de 10 kilómetros por hora.

El mismo principio se emplea en todos los casos de aceleración y de retardación.

Por ejemplo, en el caso de un cuerpo que cae, la *distancia* á que debe caer para adquirir una velocidad dada, está como el *cuadrado* de esta velocidad; pero el *tiempo* requerido es simplemente proporcional á la *velocidad*. También si se arroja un cuerpo verticalmente hacia arriba con una velocidad dada, la *altura* á la cual se eleva hasta que la gravedad destruya esa velocidad, estará como el cuadrado de la velocidad, pero el tiempo será simplemente proporcional á la velocidad.

**Art. 20** (a). Cuando un cuerpo parte del reposo y se mueve bajo la acción de una fuerza constante, durante un tiempo $t$ adquiere una velocidad, $v$, su velocidad media durante el tiempo, $t$, es ½ $v$; y la distancia recorrida es $s = ½\ vt$. Como $mv = ft$ (art. 12), tenemos:

$$\frac{mv^2}{2} = mv \times \frac{v}{2} = ft\,\frac{v}{2} = fs.$$

(*N. del T.* — Es decir, que el trabajo es igual á la mitad de la fuerza viva.)

$$\text{Como } fs = k = \frac{mv^2}{2};$$

se tiene

$$\frac{fs}{t} = \frac{mv^2}{2t} = \frac{mv}{2} \times \frac{v}{t} = \frac{mv}{2} \times a = \frac{mv}{2} \times \frac{f}{m};$$

ó bien: **la cantidad de trabajo en la unidad de tiempo** ó la proporción del trabajo

= á la mitad de la cantidad de movimiento × aceleración

= á la mitad de la cantidad de movimiento × intensidad de la fuerza.

En otras palabras, si una masa de $m$ kg se mueve con velocidad de $v$ metros por seg, tiene una cantidad de movimiento de $mv$ kilográmetros por seg y la energía de $\frac{mv^2}{2} = fs$, es decir, á la cantidad de trabajo hecho con ella para darle la

* Este no es el caso en la práctica.

velocidad $v$; é igual cantidad de trabajo debe hacerse para traer el cuerpo al reposo.

Así, si $m=4$ kg, y $v=$velocidad inicial$=12$ ms por seg; tenemos $mv=4\times12=48$ kgms por segundo, y $fs=\frac{mv^2}{2}=mv\times\frac{v}{2}=48\times6=288$ kilográmetros.

Escogiendo diferentes fuerzas, $f$, para traer esta masa al reposo, se obtienen diferentes aceleraciones, diferentes proporciones de trabajo, etc.

**La cantidad de movimiento, $mv$, en cualquier momento**, es necesariamente doble de la cantidad de movimiento media, $\frac{mv}{2}$, que la masa tiene durante el tiempo, $t=\frac{v}{a}$ en que adquiere ó pierde la velocidad, $v$, bajo la acción de cualquier fuerza constante, $f$.

Sea el peso de un cuerpo que cae$=$W, y la aceleración de la gravedad$=g$. Entonces $W\times\frac{v}{2}\times\frac{v}{g}=$ peso × velocidad media × tiempo de caída = peso × distancia (altura) de caída $=W\times\frac{v^2}{2g}=$ al trabajo hecho $=\frac{W}{g}\times\frac{v^2}{2}=m\times\frac{v^2}{2}$ $=\frac{mv^2}{2}=$ energía cinética adquirida.

**Art. 21 (a). La energía es indestructible.** La energía empleada en el trabajo no se destruye. Se comunica á otros cuerpos ó se acumula en el cuerpo mismo, ó una parte se transmite y el resto se acumula. Pero aunque la energía no se pueda destruir, puede hacerse inútil. Así, un tren en movimiento al pararse en una vía á nivel cambia su energía cinética por otra energía de la misma especie, á saber; el calor inútil debido al frotaniento de los rieles, los frenos y cilindros; y este calor, aunque no está *destruído*, se disipa en la tierra y en el aire de modo que prácticamente es irrecuperable.

**Art. 22 (a). La energía potencial** ó energía posible, se puede definir como energía acumulada. Elevamos un cuerpo del peso de un kilogramo á un metro de altura consumiendo en él un kilográmetro de energía. Pero este kilográmetro se acumula en el « sistema » compuesto de la tierra y el cuerpo como un aumento á su provisión de energía potencial.

**(b)** La energía potencial de un « sistema » de cuerpos (tales como la tierra y un peso elevado sobre ella, ó las moléculas de una masa de pólvora, ó las de un resorte torcido) depende de la *posición* relativa de esos cuerpos y de sus *tendencias* á cambiar esas posiciones. La energía cinética de un sistema (como la tierra ó un tren de carros movible) depende de las masas de sus cuerpos y de sus movimientos relativos entre sí. Ejemplos comunes de la energía potencial son el peso ó resorte de un reloj cuando se le ha dado toda ó parte de la cuerda y cuando está andando ó no. El agua encerrada en un receptáculo, la presión del vapor en una caldera y la energía explosiva de la pólvora. Tenemos energía mecánica en el caso del peso, del resorte y el agua; energía calorífica en el caso del vapor, y energía química en el de la pólvora.

**(c)** En muchos casos podemos estimar la energía potencial total de un sistema. Así (sin ocuparnos de la resistencia del aire), la energía explosiva de una libra de pólvora es$=$al peso de cualquiera bala de cañón que se nos dé × la altura á la cual la fuerza de esta pólvora la podría arrojar$=$peso de la bala × (el cuadrado de la velocidad inicial que le comunica la explosión) ÷ $2g$. Pero en otros casos sólo nos interesa encontrar cierta parte *limitada* de la energía potencial *total*. Así, la energía potencial total de un reloj de peso * no se agotará hasta que el peso no llegue al centro de la tierra; pero nosotros sólo nos ocupamos de la parte de dicha energía acumulada en el reloj al darle cuerda, la cual será transformada en energía cinética al desarrollarse la cuerda y descender el peso. Esta parte es$=$al peso × la altura desde la cual tiene que caer$=$al peso × (el cuadrado de la velocidad que adquiriría al caer *libremente* desde esa altura) ÷ $2g$.

**(d)** Hay muchos casos, tratándose de energías en las cuales podemos titubear respecto á cuál de las palabras « cinética » ó « potencial » es más apropiada. Así, al considerar la presión del vapor en una caldera, se cree que es debida al movimento violento de las moléculas del vapor que golpean la superficie interior de la caldera, y desde este punto de vista deberíamos llamarla energía cinética del vapor. Pero al mismo tiempo, la caldera permanece estacionaria, y hasta que no se per-

* Por conveniencia hablamos de la energía de un sistema de cuerpos (la tierra y el peso del reloj) como residiendo sólo en uno de los cuerpos.

mita la salida del vapor de la caldera, no hay evidencia exterior de la energía en forma de trabajo. La energía permanece estacionada en la caldera dispuesta para ser aplicada. Desde este punto de vista podemos llamar la energía del vapor así encerrado energía *potencial*.

(c) Parece racional suponer que los conocimientos ulteriores acerca de la naturaleza de otras formas de energía, aparentemente potencial (como la del vapor), ponen de manifiesto que toda energía es finalmente cinética.

**Art. 23 (a).** Hay mucha **confusión de ideas** respecto á las acciones llamadas en mecánica **fuerza, energía, potencia**, etc. Esto viene de que en el lenguaje ordinario se usan indistintamente estos términos para expresar una misma idea. Así, comúnmente hablamos de la fuerza de una bala de cañón al atravesar el aire, queriendo significar, sin embargo, la fuerza repulsiva que se *ejercería* entre una bala y un edificio, etc., si se pusieran en contacto. Esta fuerza tendería á mover una parte del edificio en la dirección de la bala y movería á la bala hacia atrás (esto es, retardaría su movimiento hacia adelante); pero esta gran *fuerza* repulsiva no existe hasta que la bala choque con el edificio. En verdad, no podemos siquiera decir por la velocidad y peso de la bala cuál sería la intensidad de la fuerza, pues ésta depende de la resistencia, etc., del edificio. Si el edificio es de vidrio, la fuerza puede ser tan leve que apenas retarde el movimiento de la bala perceptiblemente, mientras que si el edificio ó la obra es un terraplén, la fuerza será mucho mayor y puede retardar el movimiento de la bala tan rápidamente que la pare antes de moverse unos centímetros más.

La bala en movimiento tiene una gran *energía* (cinética), pero la única *fuerza* que ejerce durante su carrera, es la comparativamente leve que se requiere para apartar las moléculas de aire.

La energía de la bala y, por lo tanto, el trabajo total que ella puede realizar son independientes de la naturaleza del obstáculo que encuentra; pero, desde que el trabajo es el producto de la resistencia que se presenta y de la distancia recorrida mientras se la destruye, esta distancia debe estar en razón inversa de la resistencia que se presenta ó, lo que es lo mismo, en razón inversa de la fuerza que necesita la bala para equilibrar esa resistencia. Como el trabajo en kilográmetros = fuerza en kg × distancia recorrida en metros, tenemos :

$$\text{fuerza en kgs} = \frac{\text{trabajo en kilográmetros}}{\text{distancia recorrida en metros}} = \frac{\text{cantidad de trabajo}}{\text{en kilográmetros } \textit{por metro.}}$$

**Art. 24 (a). Un choque,** golpe ó colisión tiene lugar cuando un cuerpo en movimiento tropieza con otro. Lo peculiar en dichos casos, es que el *tiempo de acción* de la fuerza repulsiva debido á la colisión, es tan *corto*, que, generalmente, es imposible medirlos, y, por consiguiente, no podemos calcular la fuerza por la cantidad de movimiento producida por ella en uno ú otro de los dos cuerpos; pero desde que ambos experimentan un gran cambio en su velocidad durante este corto tiempo, sabemos que la fuerza repulsiva, que actúa entre ellos, debe ser muy grande.

Consideraremos solamente los casos de *choques directos* ó choques en los cuales los centros de gravedad de los dos cuerpos se aproximan naturalmente en línea recta, y donde la naturaleza de la superficie de contacto es tal, que la fuerza repulsiva causada por el choque obra también de un extremo á otro de aquellos centros y en la línea en que se aproximan.

(b) Esta fuerza, obrando igualmente sobre los dos cuerpos (art. 5 *f*) durante el mismo tiempo (á saber, el tiempo que dure el contacto), necesariamente produce igual y opuestos cambios en sus cantidades de movimiento ó fuerzas (art. 12). Por consiguiente, la cantidad de movimiento ó impulso total (ó producto de la masa × velocidad) de los dos cuerpos es siempre la misma después del choque que antes.

(c) Pero el estado en que queden los dos cuerpos, después de la colisión, depende de su elasticidad. Si pudiesen ser absolutamente inelásticos, sus velocidades, después del choque, serían iguales. En otras palabras, se moverían juntos. Si pudieran ser perfectamente *elásticos*, se separarían el uno del otro, después de la colisión, con las mismas velocidades que tenían al aproximarse antes de la colisión.

(d) Entre estos dos extremos (los cuales jamás se realizan perfectamente en la práctica), hay todos los grados posibles de elasticidad, con correspondientes diferencias en el resultado del fenómeno, ó manera de conducirse los cuerpos. Esta materia, especialmente la del *choque indirecto*, es muy complicada, pero rara vez se presenta en la ingeniería práctica civil.

(e) « En algunos experimentos hechos con cuidado en el arsenal de Portsmouth

(Inglaterra), un hombre de mediana resistencia, golpeando con una maza de 8.10 kg de peso, cuyo mango era de 1.10 m de largo, apenas hizo penetrar un perno 3 mm en cada golpe, y se necesitó una presión tranquila de 107 toneladas simplemente apoyadas sobre el perno, para hacerlo entrar la misma cantidad; pero al agregarle un pequeño peso, la hizo entrar completamente. »

## GRAVEDAD, CAÍDA DE LOS CUERPOS

**Cuerpos que caen verticalmente.** Un cuerpo que cae libremente en el vacío al partir del reposo, adquiere, al fin del primer segundo, una velocidad como de 9.81 m por segundo, y en cada segundo subsiguiente una velocidad adicional ó aceleración como de 9.81 m por segundo. En otras palabras, la velocidad recibe *en cada segundo* una aceleración de 9.81 m por segundo. Esta proporción es generalmente llamada **aceleración de la gravedad** y se la designa por **g**. Aumenta, cada segundo, como 9.78 m en el ecuador y como 9.90 m en los polos. En la latitud de Londres es de 9.81 m. Estos son los cálculos al nivel del mar; pero á una altura de 8 kilómetros sobre ese nivel, disminuye 1 parte en 400. Para la mayor parte de los usos ordinarios se puede calcular en 9.81 m.

**Observación. A causa de la resistencia del aire** ninguna de las reglas que siguen dan resultados perfectamente exactos en la práctica, especialmente en grandes velocidades. Mientras mayor sea la densidad del cuerpo más exacto será el resultado. El aire opone resistencia á la elevación y á la caída de los cuerpos.

**Si se lanza un cuerpo verticalmente hacia arriba** con una velocidad dada, se elevará á la misma altura de la que debería caer para adquirir dicha velocidad, y en cada segundo se retardará su velocidad 9.81 m por segundo. Su velocidad media ascendente será la mitad de la de salida, como en todos los otros casos de velocidad uniformemente retardada. Cayendo adquirirá la misma velocidad con que salió y en el mismo tiempo. Véase la observación anterior.

### Velocidad adquirida

$$\left.\begin{array}{l}\text{en un tiempo dado}\\ \text{desde una altura de caída dada partiendo del reposo}\\ \text{en una altura de caída dada desde el reposo y un tiempo dado}\end{array}\right\} = \begin{cases} g \times \text{tiempo} \\ \sqrt{2g \times \text{altura de caída}} \\ \dfrac{2 \text{ veces altura de caída}}{\text{tiempo}} \end{cases}$$

### Tiempo requerido

$$\text{para adquirir una velocidad dada} = \frac{\text{velocidad dada}}{g}$$

$$\left.\begin{array}{l}\text{para caer de una altura dada partiendo del reposo}\\ \text{para bajar de una altura de caída dada partiendo del reposo ó no}\end{array}\right\} = \begin{cases} \sqrt{\dfrac{\text{altura de caída}}{\frac{1}{2}\,g}} = \dfrac{\text{altura de caída}}{\frac{1}{2} \text{ velocidad final}} \\ \dfrac{\text{altura de caída}}{\text{velocidad media}} = \dfrac{\text{altura de caída}}{\frac{1}{2}(\text{vel inicial} + \text{vel final})} \end{cases}$$

### Altura de caída

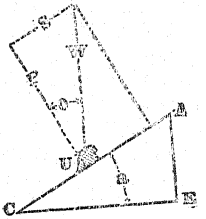
$$\left.\begin{array}{l}\text{recorrida en un tiempo dado (partiendo del reposo)}\\ \text{en tiempo dado (partiendo del reposo ó no)}\end{array}\right\} = \begin{cases} \text{tiempo} \times \tfrac{1}{2} \text{ velocidad final} = \text{tiempo}^2 \times \tfrac{1}{2}\, g \\ \text{tiempo} \times \text{velocidad media} = \\ = \text{tiempo} \times \dfrac{\text{velocidad inicial} + \text{veloc final}}{2} \end{cases}$$

$$\left.\begin{array}{l}\text{requerida para una velocidad dada}\\ \text{(partiendo del reposo)}\end{array}\right\} = \frac{\text{velocidad}^2}{2g}$$

$$\left.\begin{array}{l}\text{durante cualquier segundo dado}\\ \text{contado desde el origen del}\\ \text{movimiento, es decir, del reposo}\end{array}\right\} = g \times (\text{número del segundo (1, 2, etc.)} - \tfrac{1}{2}).$$

| Cuadro en *metros* calculando $g=9.81$ m. | Al fin del segundo. 1º | 2º | 3º | 4º | 5º | 6º | 7º | 8º | 9º | 10º |
|---|---|---|---|---|---|---|---|---|---|---|
| Velocidad adquirida al fin de cada segundo..... | 9.81 | 19.62 | 29.43 | 39.24 | 49.05 | 58.86 | 68.67 | 78.48 | 88.29 | 98.10 |
| Espacio recorrido durante cada segundo por separado..... | 4.90 | 14.70 | 24.50 | 34.30 | 44.10 | 53.90 | 63.70 | 73.50 | 83.30 | 93.10 |
| Espacio recorrido desde el origen del movimiento hasta el fin del segundo de que se trata..... | 4.90 | 19.60 | 44.10 | 78.40 | 122.50 | 176.40 | 240.10 | 313.60 | 396.90 | 490.00 |

**Descenso en planos inclinados.** Cuando se coloca un cuerpo U sobre un plano inclinado AC, todo su peso W no se empela en comunicarle velocidad (como cuando los cuerpos caen verticalmente), una porción de él P (= W × coseno de, $c$ = W × coseno de $a$ *) se emplea en ejercer una presión normal al plano; mientras que la componente S (= W × seno $o$ = W × seno $a$ *) solamente obra sobre U en dirección paralela á la superficie AC del plano y tiende á hacerlo descender por él



La aceleración comunicada á un cuerpo dado, en un tiempo dado, es proporciona á la fuerza que se ejerce sobre el cuerpo en la dirección de la aceleración. Por consiguiente, si representamos por W en escala, la aceleración $g$ (digamos 9.81 m por segundo), que la gravedad comunicaría á U en un segundo cayendo libremente, entonces la línea S representará en la misma escala la aceleración por segundo que la fuerza de deslizamiento S comunicará al cuerpo por el plano si no hubiera frotamiento. Tenemos, por consiguiente, que la aceleración *teórica* en el plano inclinado $= g$ sen $a$.

Por consiguiente nos basta con substituir $g$ sen $a$ en lugar de $g$ y la longitud del plano inclinado AC en lugar de la correspondiente altura vertical del plano AE en las últimas ecuaciones para obtener las velocidades, etc., como sigue para **un plano inclinado sin tener en cuenta el rozamiento.**

### Velocidad adquirida en el descenso

$$\text{en un tiempo dado} = \left.\begin{array}{c}\text{la velocidad adquirida en la caída vertical}\\ \text{durante el mismo tiempo}\end{array}\right\} \times \text{sen } a$$

$$= g \times \text{sen } a \times \text{tiempo.}$$

$$\left.\begin{array}{c}\text{en una longitud del plano dada}\\ \text{(como AC) á partir del reposo}\end{array}\right\} = \frac{\text{AC}}{\frac{1}{2}\text{ tiempo}}$$

$$= \left.\begin{array}{c}\text{velocidad adquirida ca-}\\ \text{yendo libremente por la}\\ \text{altura vertical AE co-}\\ \text{rrespondiente}\end{array}\right\} \sqrt{2g \times \text{AE}}$$

$$= \sqrt{2g \text{ sen } a \times \text{AC}}.$$

* Porque $o$ y $a$ son iguales.

### Tiempo necesario

$$\left.\begin{array}{l}\text{para adquirir una velocidad}\\ \text{dada en el plano}\end{array}\right\} = \frac{\text{velocidad dada}}{g \text{ sen } a}$$

$$\left.\begin{array}{l}\text{para recorrer una longitud dada}\\ \text{(como AC) partiendo del reposo}\end{array}\right\} = \frac{\text{longitud AC}}{\frac{1}{2} \text{ veloc final}} = \sqrt{\frac{\text{long AC}}{\frac{1}{2} g \text{ sen } a}}$$

$$= \frac{\text{tiempo necesario para caer por la altura vertical correspondiente AE}}{\text{sen } a}$$

$$\left.\begin{array}{l}\text{para recorrer una longitud del plano}\\ \text{dada, partiendo del reposo ó no}\end{array}\right\} = \frac{\text{longitud dada en el plano}}{\text{velocidad media por el plano}}$$

$$= \frac{\text{longitud dada del plano}}{\frac{1}{2} \text{ (vel inicial + vel final)}}$$

$$\textbf{Coseno a} = \frac{\text{base EC}}{\text{longitud AC}} = \frac{\text{proyección EC de la longitud AC}}{\text{longitud AC}} = \frac{\sqrt{\overline{AC}^2 - \overline{AE}^2}}{AC}$$

$$\textbf{Seno a} = \frac{\text{altura AE}}{\text{longitud AC}} = \frac{\text{altura correspondiente á cualquier otra longitud AC}}{\text{esa longitud AC}} =$$

$$= \frac{\sqrt{\overline{AC}^2 - \overline{EC}^2}}{AC}.$$

### Longitud AC

$$\left.\begin{array}{l}\text{recorrida en un tiempo dado}\\ \text{partiendo del reposo}\end{array}\right\} = \text{tiempo} \times \tfrac{1}{2} \text{ velocidad final por el plano}$$

$$= \text{tiempo}^2 \times \tfrac{1}{2}\, g \text{ sen } a.$$

$$\left.\begin{array}{l}\text{recorrida en un tiempo dado}\\ \text{partiendo del reposo ó no}\end{array}\right\} = \text{tiempo} \times \text{velocidad media por el plano}$$

$$= \text{tiempo} \times \tfrac{1}{2} \text{ (vel inicial + vel final)}$$

$$\left.\begin{array}{l}\text{que debe recorrer un cuerpo para adquirir}\\ \text{partiendo del reposo una velocidad dada}\end{array}\right\} = \frac{\text{velocidad dada}^2}{2g \text{ sen } a}.$$

**En la práctica, al movimiento de descenso se opone siempre el rozamiento; para tomar en cuenta su efecto** debe substituirse en las ecuaciones del plano inclinado en lugar de ($g$ sen $a$) el valor siguiente :

$g \times$ (sen $a$ — (cos $a \times$ coeficiente de rozamiento)). La razón es la siguiente :

**Rozamiento** = presión normal P $\times$ coeficiente de rozamiento
= peso W $\times$ cos $a \times$ coeficiente de rozamiento

y, por consiguiente, la aceleración $g$ debida á la gravedad se disminuirá por el rozamiento = $g$ cos $a \times$ coeficiente de rozamiento.

La **resultante** entre la fuerza S que hace deslizar el cuerpo y la de rozamiento que se opone, es :

= velocidad teórica (del descenso producida por la fuerza S) — efecto del rozamiento
= ($g$ sen $a$) — ($g$ cosen $a \times$ coeficiente de rozamiento)
= $g$ (sen $a$—cosen $a \times$ coeficiente de rozamiento).

# PÉNDULOS

El número de oscilaciones que diferentes péndulos hacen en cualquier lugar, en un tiempo dado, está en razón inversa de las raíces cuadradas de sus longitudes; así, si uno de ellos es 4, 9 ó 16 veces más largo que el otro, su raíz cuadrada será 2, 3 ó 4, y el número de oscilaciones será $^1/_2$, $^1/_3$ ó $^1/_4$ de las que hacía el péndulo de longitud 1. El tiempo en que diferentes péndulos hacen una oscilación, está en razón directa de la raíz cuadrada de sus longitudes. Así, si uno es 4, 9 ó 16 veces más largo que otro, su raíz cuadrada será 2, 3 ó 4 veces mayor y así será también el tiempo que emplea en hacer una oscilación. La longitud del péndulo que mide segundos al nivel del mar, en el vacío, á la latitud de Londres (51½° N) es 39.1393 pulgadas (.9941 m); y en la latitud de Nueva York (40 $^3/_4$° N) 39.1013 pulgadas (.9931 m). En el ecuador es como $^1/_{10}$ de pulgada (2½ mm) más corto y en los polos como $^1/_{10}$ de pulgada (2½ milímetros) más largo. Podemos decir que para experiencias de pocos segundos, la longitud del péndulo que mide segundos, en cualquier lugar y al aire libre, es, con una aproximación suficiente, de .990 m, y el que mide ½ segundo, de .2476 m; y podemos suponer que las oscilaciones largas y cortas del mismo péndulo son hechas en el mismo tiempo, como en efecto lo son con muy poca diferencia. Para medir profundidades ó distancias por medio del sonido, se puede hacer un péndulo de segundos suficientemente exacto con una piedra (un pedazo de metal en forma de disco es mejor) y un hilo suspendido de un alfiler ó un clavo delgado común. La longitud de .99 m debe medirse desde el centro de la piedra. Al comenzar las oscilaciones no debe impulsarse la *piedra ó disco;* simplemente *abandonarlo* á su propio peso después de separar la cuerda tesa de su posición vertical á una altura suficiente.

(*N. del T.* — **Para tener en milímetros** la longitud de un péndulo que haga un número de oscilaciones dadas en un minuto : divídase el número 3,571,875 por el cuadrado del número de oscilaciones, y el cociente es la longitud buscada del péndulo en milímetros. Ej. : supongamos un péndulo que haga 100 oscilaciones por minuto : dividiendo á 3,571,875 por el cuadrado de 100 que es 10,000, resultan 357.19 milímetros para la long del péndulo que se desea. Esta es la regla que da el autor convertida al sistema métrico.)

**Observación 1.ª** Practicando con un péndulo de segundos de un reloj, ó con uno preparado como se ha dicho, una persona aprenderá pronto á contar 5 en el tiempo de un segundo, y por algunos segundos sucesivos; y podrá también de este modo dividir el segundo en 5 partes iguales; ambas cosas pueden ser útiles algunas veces para cálculos aproximados cuando no se tiene péndulo á la mano.

## Centro de oscilación.

**Observación 2.ª** Cuando un péndulo ó cualquiera otro cuerpo suspendido oscila ligero ó despacio, es claro que las moléculas que están lejos del punto de suspensión se mueven más ligero que las que están cerca de él. Pero hay un punto tal en el péndulo, que, si *todas* las demás moléculas del péndulo se encontraran en él, y se movieran con la misma velocidad actual, ni el número de oscilaciones, ni su velocidad angular cambiarían. Este punto se llama *el centro de oscilación.* No es el mismo que *el centro de gravedad* y está siempre más lejos que él del punto de suspensión. La distancia entre este punto y el punto de suspensión se encuentra así : Supongamos al cuerpo dividido en muchas partes pequeñas (mientras mayor número y más pequeñas mejor). Búsquese el peso y el centro de gravedad de cada parte y la distancia de cada uno de esos centros de gravedad al punto de suspensión. Elévese al cuadrado cada una de estas distancias y multiplíquese cada cuadrado por el peso de la parte correspondiente del cuerpo. Súmense todos estos productos parciales y llámese *p* á esa suma; luego multiplíquese el peso del cuerpo entero por la distancia de su centro de gravedad al punto de suspensión. Llámese *g* el producto; divídase *p* por *g*. La suma *p* es el **momento de inercia** del cuerpo, y si se divide por su peso la raíz cuadrada del cociente será el **radio de giro** del cuerpo.

## Velocidad angular.

Cuando un cuerpo da vueltas alrededor de cualquier eje, las partes que se encuentran más distantes de ese eje se mueven con más velocidad que aquellas que están más cerca de él. Por lo tanto, no podemos asignar una velocidad lineal

fija en pies ó metros por segundo ó en millas ó kilómetros por hora y que pueda aplicarse á *cada una de sus partes*. Pero cada parte del cuerpo recorre una circunferencia entera ó un ángulo de 360° en el mismo tiempo. Por consiguiente todas las partes tienen *la misma velocidad angular* por segundo y dan el mismo número de *revoluciones* por seg alrededor del eje. Esto se llama la velocidad angular. Los autores científicos la miden por la longitud del arco descrito por cualquier punto en el cuerpo en un tiempo dado, como por ejemplo en un segundo; apreciando la longitud del arco por el número de veces que contiene la longitud de *su propio radio*. Cuando se mide de este modo tenemos

$$\text{La velocidad angular en radios por segundo} = \frac{\text{La velocidad lineal (en pies ó metros) por segundo.}}{\text{Longitud del radio (en pies ó metros).}}$$

En este caso, como queda dicho, la velocidad angular es la misma para todos los puntos del cuerpo, porque las velocidades de varios puntos están en razón directa de sus radios ó distancias al eje de revolución.

En cada revolución, cada punto describe la circunferencia del círculo en el cual gira $=2\pi r$ ($\pi=3.1416$, etc.; $r$=radio de dicho círculo); por consiguiente, si el cuerpo hace $n$ revoluciones por segundo, la longitud del arco descrito por cada punto en un segundo es $2\pi rn$; y la velocidad angular del cuerpo, ó la velocidad *lineal*, de cualquier punto *medido con su propio radio*, es

$$a = \frac{2\pi rn}{r} = 2\pi n = 6.2832 \times \text{el número de revoluciones por } \textit{segundo} =$$

$$.1047 \times \text{el número de revoluciones por } \textit{minuto}.$$

## Momento de inercia.

Supongamos un cuerpo girando alrededor de un eje, como una piedra de amolar, ú oscilando, como un péndulo. Supongamos que la distancia del eje de revolución (que en el péndulo es el punto de suspensión), á cada molécula en particular del cuerpo, ha sido medida, y que el cuadrado de cada una de dichas distancias ha sido multiplicado por el peso de sus respectivas moléculas.

La suma de todos estos productos es el momento de inercia del cuerpo. Esto

$$\textbf{Momento de inercia} = \left\{\begin{array}{c}\text{la suma para}\\ \text{todas las moléculas}\end{array}\right\} \text{de} \left\{\begin{array}{c}\text{peso}\\ \text{de}\\ \text{moléculas}\end{array}\right\} \times \begin{array}{c}\text{Cuadrado de las distancias de la molécula}\\ \text{al eje de revolución}\end{array}$$

ó, $I=\Sigma d^2 w$.

Los autores científicos, al calcular el momento de inercia usan frecuentemente la *masa* de cada molécula; que es $= \frac{\text{su peso}}{\text{aceleración } (g) \text{ de la gravedad} = 9.81 \text{ m}}$ en lugar de su peso.

En la práctica debemos suponer al cuerpo divido en partes de una pulgada cúbica ó un centímetro cúbico (ó cualquiera otro volumen pequeño) cada uno; y usar éstos en lugar de las partículas infinitamente pequeñas que supone la teoría. Mientras más pequeñas se tomen estas partes, más exacto será el resultado.

Cuando se quiere el momento de inercia de una simple *superficie* (en vez de la de un *cuerpo*), suponemos la superficie dividida en un número de *áreas* pequeñas, y empleamos éstas en lugar de los *pesos* de las moléculas del cuerpo.

$$\textbf{Momento de inercia} = \frac{\text{peso del cuerpo}}{\text{ó}}{\text{área de la superficie}} \times \begin{array}{c}\text{cuadrado del radio}\\ \text{de giro.}\end{array}$$

(*N. del T.* — El **radio de giro** de un cuerpo es la distancia á que sería preciso colocar un punto material de *una masa igual á la del cuerpo* para que tuviese *el mismo momento de inercia del cuerpo*.)

## Tabla de radios de giro.

| Cuerpo. | Girando alrededor de | Radio de giro. |
|---|---|---|
| **Cualquier cuerpo ó figura.** | Cualquier eje dado. | $\sqrt{\frac{\text{Momento de inercia alrededor del eje dado}}{\text{Peso del cuerpo, ó área de su superficie}}}$ |
| **Cilindro sólido.** | Su eje longitudinal. | Radio del cilindro $\times \sqrt{\frac{1}{2}}$. |
| Ídem. | Un diám medio entre sus extremos. | = Radio del cilindro $\times$ .7071 (más ó menos). |
| Ídem infinitamente corto (superficie circular). | Un diámetro. | $\sqrt{\frac{\text{Longitud}^2}{12} + \frac{\text{radio}^2 \text{ del cilindro}}{4}}$. $\frac{\text{Radio del cilindro}}{2}$. |
| **Cilindro hueco.** | Su eje longitudinal. | $\sqrt{\frac{\text{Radio interior}^2 + \text{radio exterior}^2}{2}}$. |
| Ídem infinitamente delgado. | Ídem. | Radio del cilindro. |
| Ídem de cualquier espesor. | Un diám medio entre sus extremos. | $\sqrt{\frac{\text{Radio inter}^2 + \text{radio exter}^2}{4} + \frac{\text{longitud}^2}{12}}$. |
| Ídem infinitamente delgado. | Ídem. | $\sqrt{\frac{\text{Radio}^2 \text{ del cilindro}}{2} + \frac{\text{longitud}^2}{12}}$. |
| Ídem infinitamente delgado é infinitamente corto (circunferencia de un círculo). | Un diámetro. | Radio del cilindro $\times \sqrt{\frac{1}{2}}$. = Radio del cilindro $\times$ .7071 próximamente |
| **Esfera sólida.** | Un diámetro. | $\sqrt{\frac{\text{Radio}^2 \text{ de la esfera}}{2.5}}$ = radio de la esfera $\times \sqrt{.4}$. = radio de la esfera $\times$ .63246 próximamente. |
| **Esfera hueca** de cualquier espesor. | Un diámetro. | $\sqrt{\frac{2\ (\text{radio exterior}^5 - \text{radio interior}^5)}{5\ (\text{radio exterior}^3 - \text{radio interior}^3)}}$. |
| Ídem delgada. | Ídem. | Aproximado (radio exterior + radio interior) $\times$ .4085. |
| Ídem infinitamente delgada (superficie esférica). | Un diámetro. | Radio de esfera $\times \sqrt{\frac{2}{3}}$. = Radio de esfera $\times$ .8165 aproximadamente. |
| **Línea recta**, $ab$.   | Cualquier punto, $x$, en su longitud. | $\sqrt{\frac{ax^3 + xb^3}{3ab}}$. |
| | Cualquier extremo, $a$ ó $b$. | Longitud $ab \times \sqrt{\frac{1}{3}}$. = Longitud $ab \times$ .5775 aproximadamente. |
| | Su centro, $c$. | $ac \times \sqrt{\frac{1}{3}}$. = Longitud $ab \times$ .2887 aproximadamente. |

**Tabla de radios de giro.** (Continuación.)

| Cuerpo. | Girando alrededor de | Radio de giro. |
|---|---|---|
| **Cono sólido.** | Su eje. | Radio de la base del cono $\times \sqrt{.3}$. = Radio de la base del cono $\times .5477$. |
| **Plancha circular, de sección** transversal rectangular. | Véase cilindro sólido. | Para el *espesor* de la plancha ó círculo medido perpendicularmente al plano de la circunferencia tómese la *longitud* del cilindro. |
| **Anillo circular** de sección transversal rectangular. | Véase cilindro hueco. | |
| **Cuadrados, rectángulos y otras superficies.** | Para los radios de giro *mínimos* alrededor de los ejes más *largos*, véanse páginas siguientes. | |

**Relaciones entre el radio menor de giro, $r$, y el lado menor, $D$.**

En una sección transversal cualquiera, sea :

$I$ = al menor momento de inercia;
$a$ = área;
$r = \sqrt{I/a}$ = radio menor de giro;
$D$ = diámetro ó lado menor externo;
$d$ = diámetro ó lado menor interno;
$B$ = diám ó lado mayor externo;
$b$ = diám ó lado mayor interno;
$t$ = espesor del macizo;
$c = D/t$; $1/12 = .0833$;
$m = B/D$; $\sqrt{12} = 3.4641$.

Entonces se tienen las siguientes relaciones :

| Sección transversal. | $r$ | $r^2$ | $\frac{D}{r}$ | $\left(\frac{D}{r}\right)^2$ |
|---|---|---|---|---|
|  Cuadrado sólido. | $\frac{D}{\sqrt{12}}$ | $\frac{D^2}{12}$ | $\sqrt{12}$ | 12 |
|  Cuadrado hueco * de espesor uniforme. | $\sqrt{\frac{D^2+d^2}{12}}$ | $\frac{D^2+d^2}{12}$ | $\sqrt{\frac{12\,D^2}{D^2+d^2}}$ * | $\frac{12\,D^2}{D^2+d^2}$ * |
| Rectángulo sólido. | $\frac{D}{\sqrt{12}}$ | $\frac{D^2}{12}$ | $\sqrt{12}$ | 12 |
|  Rectángulo hueco † de espesor uniforme. | $\sqrt{\frac{D^2B-d^2b}{12(DB-db)}}$ | $\frac{D^2B-d^2b}{12(DB-db)}$ | $\sqrt{\frac{12D^2DB-db}{D^2B-d^2b}}$ † | $12D^2\frac{DB-db}{D^2B-d^2b}$ † |
|  Círculo sólido. | $\frac{D}{4}$ | $\frac{D^2}{16}$ | 4 | 16 |
|  Círculo hueco ** de espesor uniforme. | $\sqrt{\frac{D^2+d^2}{16}}$ | $\frac{D^2+d^2}{16}$ | $4D\sqrt{\frac{1}{D^2+d^2}}$ ** | $\frac{16\,D^2}{D^2+d^2}$ ** |

★ Cuadrado hueco; $c = D/t$.

| Cuando $c$ = | 5 | 10 | 20 |
|---|---|---|---|
| $(D/r)^2$ = | 8.82 | 7.32 | 6.63 |

† Rectángulo hueco de espesores uniformes; $c = D/t$; $m = B/D$.

## FUERZA CENTRÍFUGA

Cuando un cuerpo *a*, fig. 1, pág. 374, se mueve en una dirección circular *abd*, tiende en cada punto, *a* ó *b*, á moverse según la tangente *at* ó *bt'* del círculo, en aquel punto. Pero en cada punto, *a*, etc., de dicha dirección es desviado de la tangente por una fuerza que obra hacia el centro *c* del círculo. Esta fuerza puede ser la tensión de una cuerda, *ca*, ó la atracción entre un planeta en *c* y su satélite *a;* ó la presión de los rieles, *ab*, hacia el centro de una curva, etc., etc. Como toda fuerza, es una acción entre dos cuerpos que tiende á separarlos ó á unirlos y que actúa igualmente sobre ambos. (Véase **Mécanica**, art. 5 *b*.) En el caso de la cuerda, ésta tira del cuerpo *a* hacia el centro *c* del clavo ó mano, etc., y del centro *c* hacia el cuerpo en *a* ó *b*, etc. En el caso de un carro en una curva la fuerza tira al carro *fuera* del centro, y los rieles lo tiran *hacia* el centro. La atracción ó impulsión que tiende á lanzar el cuerpo giratorio *hacia* el centro se llama **fuerza centrípeta**, mientras que la impulsión que tiende á alejar del centro al cuerpo se llama **fuerza centrífuga**. Estas dos « fuerzas » constituyen meramente la acción y reacción de una misma fuerza, son por tanto necesariamente iguales y opuestas; sólo pueden existir juntas. En el momento en que la tensión de la cuerda excede á su resistencia ó fuerza de cohesión, se revienta aquélla, y fuerzas centrípeta y centrífuga cesan por consiguiente instantáneamente; el cuerpo deja de estar perturbado por la fuerza que lo desvía, y se sigue moviendo con una velocidad uniforme * en una tangente *at* ó *bt'*, etc., á su trayectoria circular, en ángulo recto con la dirección que la fuerza centrífuga tenía en el momento en que cesó

(a) **Cuerpo giratorio simple**, *a*, fig. 1. Sea

$f$ = á la fuerza centrífuga ó centrípeta, en libras (ó kgs).
W = al peso del cuerpo *a*.
R = al radio *ca* de la trayectoria del *centro de gravedad* del cuerpo *a*.
$v$ = la velocidad uniforme por segundo del cuerpo *a* en su dirección circular *abd*.
$n$ = al número de revoluciones por minuto.
$g$ = á la aceleración de la gravedad = 9.81 m por segundo; 900 $g$ = 8,829 m.
$\pi$ = circunferencia ÷ diámetro = 3.1416. $\pi^2$ = 9.8696.

Entonces, para la **fuerza centrífuga**, $f$, tenemos la fórmula siguiente :

Si conocemos la velocidad $v$, por segundo : $f = \mathrm{W}\dfrac{v^2}{\mathrm{R}g}$ †..... (1

ó si conocemos el número de revoluciones por minuto : $f = \mathrm{W}\dfrac{\pi^2 \mathrm{R} n^2}{900g}$ ‡..... (2)

Sustituyendo en lugar de $\pi^2$ y $900g$ sus valores, viene : $f = .0012\ \mathrm{W}\mathrm{R}n^2$ ..... (3

(b) **Ruedas, anillos y discos.** Supongamos una rueda cortada en muy pequeños pedazos como se ve (muy exagerado) en *a*, fig. 2. Para cada pedazo *a* tenemos por la fórmula (1) : $f$ = peso W del pedazo $\times \dfrac{v^2}{\mathrm{R}g}$ ;** y si cada uno estuviese unido

---

* Despreciando el rozamiento, la acción de la gravedad, la resistencia del aire, etc.

† Si *at*, fig. 1, representa la intensidad y dirección de la velocidad $v$ del cuerpo en *a* en un segundo, al fin de un segundo el cuerpo habrá alcanzado el punto *b* (habiéndose hecho el arco *ab* = *at*), y la intensidad y dirección de la velocidad en *b* estará entonces representada por la línea *bt'* = *at* en longitud; pero difiriendo en dirección. Trazando á *cu* y *cu'* por el centro, iguales y paralelas respectivamente á *at* y *bt'*, encontramos que el *cambio en la dirección* del movimiento (sea la aceleración hacia el centro durante el segundo de que se trata) está representada por el arco *uu'*; y como el ángulo *acb* = ángulo *ucu'*, tenemos la proporción, radio R ó *ac* : *ab* ó *at* = *cu* ó *at* : arco *uu'*. En otras palabras, la aceleración *uu'* en un segundo, es : $\dfrac{at^2}{\mathrm{R}} = \dfrac{v^2}{\mathrm{R}}$; y para la fuerza que produce esta aceleración tenemos $f$ = masa del cuerpo × valor de la aceleración = masa del cuerpo × $\dfrac{v^2}{\mathrm{R}} = \mathrm{W}\dfrac{v^2}{\mathrm{R}g}$.

‡ Por medio de la fórmula (1), $f = \mathrm{W}\dfrac{v^2}{\mathrm{R}g}$; pero $v = \dfrac{2\pi \mathrm{R}n}{60}$ ; y $v^2 = \dfrac{4\pi^2\mathrm{R}^2n^2}{3{,}600} = \dfrac{\pi^2\mathrm{R}^2n^2}{900}$ Por consiguiente, $f = \mathrm{W}\dfrac{\pi^2\mathrm{R}^2n^2}{900\ \mathrm{R}g} = \mathrm{W}\dfrac{\pi^2\mathrm{R}n^2}{900\ g}$.

** Si el disco es muy angosto en el sentido del radio con relación á su diámetro *mn*, podremos tomar el centro de gravedad de cada uno de los pedazos como si estuvieran

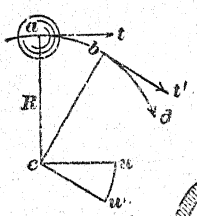

Fig. 1

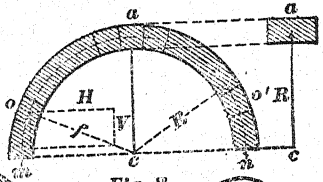

Fig. 2

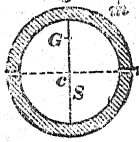

Fig. 3

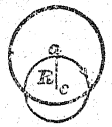

Fig. 4

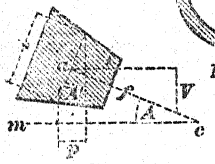

Fig. 5

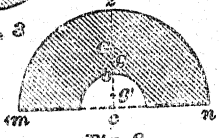

Fig. 6

Fig. 7

al centro por una cuerda, las sumas de las fuerzas en todas las cuerdas (despreciando el frotamiento de los pedazos adyacentes) sería :

F = suma de las fuerzas centrífugas de todos los pedazos ∴ = peso del disco $\times \frac{v^2}{Rg}$ ..... (4)

Pero el esfuerzo que generalmente nos interesa más en semejantes casos (p. ej., **la tensión en el anillo** en la dirección de una tangente á su circunferencia) es *mucho menor* que la intensidad teórica F obtenida por la fórmula (4), ya que en realidad es solamente $\frac{1}{6.2832}$ de ella. Porque se considera primero * que el disco se corta solamente en dos partes opuestas *m* y *n*, fig. 3, y que sus dos mitades están sujetas tan sólo por la cuerda S.

Y considerando así las cosas, tendremos entonces * :

semicircunferencia *mzn* : diámetro $mn = \frac{F}{2}$ : tensión de la cuerda S,

de manera que :

**Tensión de la cuerda** S = mitad del peso del anillo $\times \frac{v^2}{Rg} \times \frac{2}{\pi} =$ peso del anillo $\times \frac{v^2}{Rg\pi} = \frac{F}{\pi} = \frac{F}{3.1416}$ (5)

---

en una circunferencia intermedia que pasa entre los bordes interior y exterior del anillo, de manera que $R = \frac{\text{radio interior} + \text{radio exterior}}{2}$. En un anillo de espesor apreciable, este no será el caso; porque cada pedazo es un poco más ancho en su borde exterior que en el interior. (Véase la fig. 5.) Por consiguiente su centro de gravedad está un poquito fuera de la curva *mn*, fig. 2.

∴ En un anillo perfectamente en equilibrio (como en un anillo cuyo centro de gravedad coincida con su centro de rotación, como en la fig. 3), las fuerzas centrífugas de las moléculas de un lado *c* equilibran las del lado opuesto. También, tenemos aquí R = 0. Por consiguiente, considerado *como un todo*, dicho anillo no posee *fuerza centrífuga;* no hay fuerza que obre sobre el centro en ninguna dirección, por causa de la rotación. Pero si los dos centros *no coinciden* (fig. 4), entonces el anillo es un simple cuerpo rotatorio, y su fuerza centrífuga es *f* = peso del anillo entero $\times \frac{v^2}{Rg}$; siendo R la distancia entre los dos centros, y *v* la velocidad del centro de gravedad *a*. La fuerza *f* obra en la línea que une los dos centros.

* En la fig. 2, supongamos que la fuerza centrífuga de cualquier pedazo, *o*, esté representada por la diagonal *f* de un rectángulo, cuyos lados H y V, son respectivamente paralelos y perpendiculares al diámetro *mn;* H y V representan los componentes de *f*

y si el anillo se completa ahora uniendo los extremos $m$ y $n$, y si se suprime la cuerda S, entonces la tensión de la cuerda según la fórmula (5) estará dividida por igual entre $m$ y $n$. Por consiguiente cada sección transversal, $m$ ó $n$ del disco, resistirá una tensión igual á la mitad de la tensión de la cuerda; ó

$$\textbf{Tensión del anillo} = \frac{F}{2\pi} = \frac{F}{6.2832} = \frac{\text{peso del anillo} \times v^2}{6.2832\,Rg} \quad \ldots\ldots\ldots\ldots (6)$$

La fuerza centrípeta $f$, fig. 2, que sujeta una parte cualquiera $o$, del anillo, es la resultante de las dos tensiones iguales que actúan en los extremos de aquella parte.

Para apreciar la *fuerza por unidad de superficie* de las secciones transversales del anillo, tenemos:

$$\textbf{Esfuerzo por unidad} = \frac{\text{tensión en el anillo}}{\text{área A de las secciones transversales del anillo}}$$

$$= \frac{F}{6.2832\,A} = \frac{\text{peso del anillo} \times v^2}{6.2832\,ARg} \quad \ldots\ldots\ldots\ldots (7)$$

Llegaremos al mismo resultado si reflexionamos que la tensión de la cuerda S ó la *suma* de las dos tensiones en $m$ y $n$, es igual á la fuerza centrífuga $f$, de cualquiera de las dos *mitades* del anillo girando como un solo cuerpo alrededor del centro $c$. Búsquese el centro de gravedad G del medio anillo, y en la fórmula (1) úsese la velocidad de aquel punto y el radio $cG$ en lugar de la velocidad en $z$ y del radio $cz$ respectivamente; así pues :

$$\text{tensión de la cuerda} = f = \frac{\text{fuerza centrífuga}}{\text{del medio anillo}} = \frac{\text{peso del medio}}{\text{anillo}} \times \frac{(\text{velocidad en G})^2}{cG \times g}$$

y la mitad de esto es la tensión en cada sección transversal del anillo *.

Si el anillo fuera infinitamente angosto $cG$, fig. 3, sería .6366 $cz$.

Si su espesor debe tomarse en consideración, y si es de sección transversal rectangular, búsquense los centros de gravedad $g$ y $g'$, fig. 6, de todo el segmento semicircular $cz$, y del pequeño segmento $cb$ respectivamente ($cg$ = .4244 $cz$, y $cg'$ = = .4244 $cb$.

Tendremos : $$g'G = gg' \times \frac{\text{área del segmento entero } cz}{\text{área de la mitad del anillo}}.$$

Para anillos de secciones transversales, no rectangulares, empléense las fórmulas (4) (5) y (6).

**En un disco, tal como una piedra de amolar,** la tensión en cada sección transversal completa $mn$, fig. 7, es igual á la fuerza centrífuga $f$ de la *mitad* del disco. Sea W = al peso del medio disco. La distancia $cG$ del centro $c$ al centro de gravedad G del medio disco, es $cG = .4244 \times cz$; y la

$$\textbf{Tensión en } mn = f = W\frac{(\text{vel en G})^2}{\text{rad } cG \times g} = W\frac{.4244^2\ (\text{vel en } z)^2}{.4244 cz \times g}$$

$$= W\frac{.4244\ (\text{vel en } z)^2}{cz \times g} \quad \ldots\ldots\ldots\ldots (8)$$

$$= W\frac{.4244\ \pi^2 n^2 cz}{900\ g} \quad \ldots\ldots\ldots\ldots (9)$$

---

Las componentes horizontales, iguales y opuestas H de $o$, y del correspondiente pedazo $o'$, siendo paralelas á $mn$ no tienen tendencia á separar el disco en $m$ ó $n$. Por consiguiente, la tensión de una cuerda S, fig. 3, perpendicular á $mn$, es la suma de los componentes V de todos los pedazos. Para cada pedazo, fig 5 (demasiado exagerada), tenemos (siendo ángulo A = ángulo A') :

$$\text{Longitud } l \text{ del pedazo} : \text{su proyección horizontal, } p = \text{fuerza centrífuga } f, \text{ del pedazo} : \text{su componente vertical V}$$

Por consiguiente, para la mitad entera del anillo $mn$, fig. 3 (formado de dichos pedazos ó tajadas), tenemos :

$$\text{Longitud } mzn \text{ del medio disco} : \text{su proyección horizontal } mn = \text{la suma de las fuerzas centrífugas de todas las tajadas del medio disco} : \text{la suma de los componentes verticales V para todas aquellas tajadas;}$$

lo cual es idéntico á la proporción que sigue.

*Los *discos* ó *llantas* de las ruedas giratorias se hacen suficientemente fuertes para que resistan la tensión debida á la fuerza centrífuga sin ayuda de los *rayos*, los cuales tienen simplemente que soportar el *peso* de la rueda. Pero si se rompe la llanta, las fuerzas centrífugas de sus fragmentos obran totalmente sobre los rayos; y como la ruptura es siempre irregular, algunos de los rayos soportarán más de lo que les corresponde.

El valor de la fuerza por unidad de superficie en la sección $mn$ es

$$= \frac{\text{tensión en } mn}{\text{área de la sección transversal}}.$$

$$= W \frac{.4244\ (\text{velocidad en } z)^2}{\text{diám } mn \times \text{grueso del anillo} \times cz \times g} \quad \ldots\ldots\ldots (10$$

$$= W \frac{.4244\ \pi^2 n^2 cz}{\text{diám } mn \times \text{grueso ó espesor} \times 900\ g} \quad \ldots\ldots\ldots (11$$

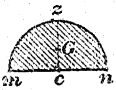

Fig. 7

$f$=á la fuerza centrípeta que actúa sobre un cuerpo giratorio simple *a*, figs. 1, 2, 4 y 5, ó sobre el semianillo ó semidisco, figs. 3, 6 y 7=á la fuerza centrífuga ejercida por dicho cuerpo.

**F**=la suma de las fuerzas centrífugas $f$ de todas las moléculas del anillo, fig. 3

**W**=peso del cuerpo.

**R**=radio *ca*, figs. 1, 4 y 5, de la trayectoria que describe el *centro de gravedad* del cuerpo.

$v$=la velocidad uniforme por segundo de que está animado el cuerpo en su trayectoria circular.

$n$=número de revoluciones por minuto.

$g$=la aceleración de la gravedad.

$\pi = \frac{\text{circunferencia}}{\text{diámetro}} = 3.1416.$

$\pi^2 = 9.8696$ próximamente.

**En una rueda en movimiento,** apoyada la llanta sobre el suelo, cada punto de la llanta está fijo *con respecto á la tierra,* mientras dura el contacto con el terreno; pero cada molécula está animada de una misma velocidad *alrededor del centro* de la rueda, considerando á éste como fijo, y por consiguiente la fuerza centrífuga no tiene efecto sobre el peso.

# ESTÁTICA

## FUERZAS

**1. Definición de la estática.** La estática, ó ciencia del equilibrio de las fuerzas, estudia los numerosos casos en que las fuerzas, que se consideran están en equilibrio, es decir, se destruyen. Por tanto, abarca todos los casos en que se dice que los cuerpos están « en reposo ».

**2. En los problemas que generalmente se presentan** á los ingenieros, ciertas fuerzas aplicadas á un cuerpo en reposo (como un puente ó un edificio) tienden á producir movimiento, ya sea en todo el cuerpo ó en una ó más de sus partes; y se necesita encontrar y aplicar otras fuerzas que destruyan la tendencia al movimiento, logrando así que el cuerpo y sus partes se mantengan en reposo. (Véase § 33, más adelante.)

**3. Equilibrio.** Supongamos un cuerpo sobre el que actúan varias fuerzas. Estas fuerzas se dicen en equilibrio, cuando combinadas no alteran ni el reposo ni el movimiento del cuerpo, ya sea considerado en su conjunto con respecto á su movimiento de traslación, ó con respecto á un movimiento de rotación referido á un punto del cuerpo ó fuera de él. (Véase § 84, más adelante.)

*4.* Un cuerpo puede estar en equilibrio con respecto á las fuerzas que se estudian, aunque no lo esté con respecto á otras. Así, una piedra sostenida entre el índice y el pulgar, está en equilibrio con respecto á estas dos presiones iguales, aun cuando se suba y baje la piedra por un exceso de fuerza muscular del brazo sobre la acción de la pesantez en la piedra. De manera semejante, en un ferrocarril á nivel, un carro se encuentra en equilibrio respecto á la pesantez y á la resistencia hacia arriba de los rieles, aun cuando el tiro de la locomotora exceda á la resistencia de la tracción.

**5. Acción molecular.** Toda fuerza aplicada á un cuerpo es prácticamente un sistema de fuerzas, á menudo paralelas, aplicado á las varias partículas del cuerpo. Así la acción ejercida por la tierra sobre un grano de arena ó sobre la luna, es, en verdad, un conjunto de fuerzas casi paralelas, ejercidas sobre las varias partículas de aquellos cuerpos; pero para mayor claridad, y tan sólo en lo que se refiere á su tendencia, para mover al cuerpo en su conjunto, concebimos aquellas fuerzas como sustituídas por una sola, igual á su suma, y obrando en una sola dirección. Al considerar así las fuerzas, suponemos que los cuerpos sean enteramente rígidos, de manera que cada una de ellas obra independiente como una « partícula » ó un « punto material ».

**6. Transmisión de fuerzas.** La presión hacia arriba del suelo sobre una piedra que reposa en él, obra directamente tan sólo sobre aquellas partículas que están más cerca del suelo. Éstas, á su vez, ejercen (prácticamente) una fuerza hacia arriba sobre las que se encuentran inmediatamente encima, y así sucesivamente, y en esta forma se transmite por toda la piedra.

**7. Cuerpos rígidos.** Al considerar rígidos á los cuerpos suponemos que las fuerzas intermoleculares mantienen las diversas partículas absolutamente en sus posiciones originales relativas.

No es *la materia* la que resiste á la ruptura, sino las fuerzas que mantienen sus partículas en posición. Así, un pedazo de hielo puede soportar una gran presión; pero sus partículas se separan fácilmente cuando una temperatura de deshielo destruye sus fuerzas de cohesión.

**8. Unidades de fuerza.** Las unidades de fuerza generalmente usadas en estática, son la de peso, como la libra ó el kilogramo. (Véanse las tablas de conversión, pág. 245.)

En estática no tenemos necesidad de considerar las masas de los cuerpos (excepto en los casos en que éstas determinan sus pesos ó la fuerza de la pesantez ejercida sobre ellos), pues los cuerpos se consideran tan sólo como el medio por donde, y á través del cual, obran las fuerzas que se consideran. Por eso en estática no se requiere la unidad de masa; como los cuerpos se consideran como « en reposo », tampoco se necesitan unidades de tiempo, velocidad, aceleración, impulso ó energía.

**9. Fuerzas; su determinación.** Una fuerza se encuentra completamente determinada cuando conocemos (1) su valor (en kg ú otra unidad de peso), (2) su dirección, (3) su sentido (véase § 10), y (4) su posición ó su punto de aplicación.

**10. Cuando una fuerza está representada por una línea**, puede hacerse que su longitud represente, por escala, la cantidad de la fuerza; y su dirección y posición pueden servir á menudo para indicar las de la fuerza, mientras que el sentido de la fuerza se puede indicar por flechas ó letras sobre la línea ó por los signos + y —.

Así, la *dirección* de las fuerzas representadas por las líneas *a* y *b*, fig. 1, son verticales, y aquellas de las *c* y *d* son horizontales. El sentido de *a* es hacia arriba, de *b* hacia abajo, de *c* hacia la derecha, de *d* hacia la izquierda. De modo que *a* y *b* son de la misma dirección, pero en sentido opuesto; lo mismo *c* y *d*. Al ocuparnos de fuerzas verticales ú horizontales, las llamamos generalmente hacia arriba ó á la derecha: **positivas**; y hacia abajo ó á la izquierda: **negativas**, como lo indican los signos + y —, en la fig. 1. Cuando se designa una fuerza por dos letras fijas á cada extremo de la línea que la representa, el sentido de la fuerza se puede indicar por el orden en que se han puesto las letras. Así, en la fig. 1, siguiendo la dirección de las flechas, tenemos las líneas *ef*, *hg*, *kl*, *nm*.

**11. Línea de acción, etc.** El punto (véase § 5) donde se supone aplicada una fuerza P (fig. 2), se llama su *punto de aplicación;* pero las fuerzas se transmiten á todo el cuerpo por medio de sus partículas (véase § 6), y el efecto de la fuerza, en lo que se refiere al cuerpo como un todo, no cambia si se la supone aplicada en un

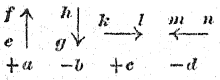

Fig. 1.

Fig. 2.

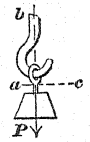

Fig. 3.

punto cualquiera *b* de su prolongación, y por tanto cualquier punto de esa línea se puede considerar como punto de aplicación. Por ejemplo, la tendencia á mover la piedra no cambia (fig. 2) aplicando la fuerza en *a* ó en *b;* y en cuanto al peso P, fig. 3, ejercerá la misma tendencia para mover el garfio, colocado arriba de aquél en *b* ó colgando en *a*. No se puede aplicar ninguna fuerza á un cuerpo en puntos fuera de su masa, como sucede en las partes vacías de la línea *ab* del garfio; no obstante, estas partes vacías pertenecen á la línea de aplicación de la fuerza. La fuerza vertical ejercida por el peso, P, se transmite al punto *b*, por medio de los momentos inclinados de la parte curva del gancho.

**12.** Aplicándole por contacto fuerzas opuestas á un cuerpo (véase art. 5 *c*, pág. 348), entra á obrar en la masa del cuerpo la fuerza intermolecular, tendiendo, ó á separarlas, y entonces se dice que las fuerzas obran por *tensión*, ó á juntarlas, se llama *compresión*. **El esfuerzo** (*tensión ó compresión*) **debido á dos fuerzas opuestas es igual á una de ellas.**

**Tensión y compresión. Tirantes, puntales, etc.** Si la acción de las fuerzas tiende á separar más las partículas del cuerpo sobre las que actúan, se dice que hay *tensión*. Si tiende á juntarlas, se dice que hay *compresión*. Una pieza larga, débil, sometida á tensión, se llama en general *cuerda*. La que trabaja por compresión se llama *poste, puntal*, etc. La que está sometida á veces á tensión y otras á compresión es una *cuerda-poste* ó *poste-cuerda*.

## MOMENTOS

**13. Momentos.** Si de cualquier punto *o* ú *o'*, fig. 4, se baja una perpendicular *oc* ú *o's* á la línea *nm*, dirección de la fuerza $P_1$, aun cuando el punto *o* ú *o'* se encuentre dentro ó fuera del cuerpo sobre el que obra la fuerza $P_1$, dicha línea *oc* ú *o's* se llama el *brazo de palanca* de la fuerza en aquel punto, y así la intensidad de la fuerza (en unidades de peso, libras ó kilogramos) se multiplica por el brazo de la palanca (en pies ó metros); el producto (pies-libras, kilográmetros) es el momento de la fuerza en aquel punto *. El momento representa la tendencia total de la fuerza á producir rotación alrededor de un punto dado. El momento de una fuerza en los puntos de su dirección es cero.

**14. Dirección de los momentos.** Desde que el *momento* de $P_1$ respecto á *o*, fig. 4, tienda á engendrar rotación (alrededor de aquel punto), en la misma dirección que las agujas de un reloj visto de frente, ó sea de izquierda á derecha, como lo indica la flecha en el círculo, *o*, el momento es **positivo** (+), pero, el momento de la misma fuerza en *o'* tiende á producir rotación en sentido contrario al del reloj y es **negativo** ( — ).

**15. El plano de un momento** es aquel en que se encuentran la dirección y el brazo de palanca de la fuerza.

**16. La resultante** ó tendencia combinada de dos ó más momentos en un mismo plano, es igual á la suma algebraica de todos los momentos.

Así, fig. 4, si las fuerzas $P_1$, $P_2$ y $P_3$ representan respectivamente 6, 5 y 3 kg, y si sus brazos de palanca *oc*, *oy*, *oe*, de sus momentos respecto *o*, fuesen de 7, 6 y 3 m, tenemos :

$$\begin{aligned} & P_1 \times oc - P_2 \times oy + P_3 \times oe \\ = \ & 6 \times 7 \ - \ 5 \times 6 \ + \ 3 \times 3 \\ = \ & 42 \ - \ 30 \ + \ 9 \ = 21 \text{ kilográmetros.} \end{aligned}$$

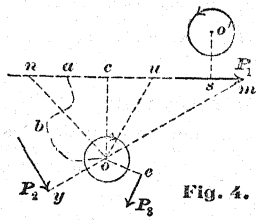

Fig. 4.

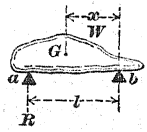

Fig. 5.

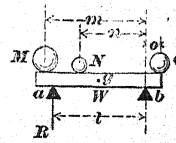

Fig. 6.

**17.** Si la suma algebraica de los momentos es cero, están en **equilibrio** y no tienden á hacer rotar el cuerpo alrededor del punto dado.

Así, en la figura 5, si W es el peso y G el centro de gravedad del cuerpo; y R la reacción hacia arriba del apoyo izquierdo *a*, tomando los momentos respecto del apoyo de la derecha, *b*, tenemos $Rl - Wx = 0$; ó bien : $Rl = Wx$. De donde $R = \frac{Wx}{l}$.

De modo análogo en la figura 6, donde W es el peso de la viga sola, y *g* el centro de gravedad de W, aquél está en el centro del espacio *l*, de manera que el brazo de palanca *bg* del peso de la viga respecto *b*, es $= \frac{l}{2}$, se toman los momentos respecto al punto *b*, así:

$$R \times l + Oo - W\frac{l}{2} - Mm - Nn = \text{cero; ó sea}$$

$$R = \frac{Mm + Nn + W\frac{l}{2} - Oo}{l}.$$

* Nótese que una fuerza muy pequeña puede tener un gran momento en un punto, mientras que una fuerza mucho mayor, pasando más cerca del mismo punto, puede tener un momento menor respecto á él, ó pasar por el punto con momento *cero*.

En la figura 7, en la que W es el peso de la viga misma, y $w$ su palanca, tomando los momentos respecto á $b$, tenemos:

$$+Rl+Oo-Nn-Ww+Mm=0;$$

$$\text{De donde, la reacción en } a=R=\frac{Ww+Nn-Mm-Oo}{l}.$$

En todo caso, si W es el peso combinado; G el centro común de gravedad de la viga y sus cargas, y $x$ la distancia horizontal de aquel centro al apoyo $b$ de la derecha; y si $l$ es la abertura; R la reacción del soporte izquierdo, $a$, y R' la del soporte $b$ de la derecha, tenemos:

$$R=\frac{Wx}{l};\qquad R'=W-R.\qquad \text{Si } x=\frac{l}{2},\qquad R=\frac{W}{2}=R'.$$

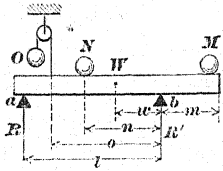

**Fig. 7.**

Nótese que los momentos de dos ó más fuerzas respecto á un punto dado, pueden estar en equilibrio, aun cuando las fuerzas mismas no lo estén. (Véase § 84, más adelante.)

**18. Centro de los momentos.** En lo que se relaciona con el equilibrio de los momentos, es indiferente el punto que se escoja como centro, pero conviene generalmente escogerlo en la dirección de una (ó más, si hay fuerzas concurrentes, véase § 19) de las fuerzas desconocidas, pues así eliminamos dicha fuerza, ó fuerzas, de la ecuación.

## CLASIFICACIÓN DE LAS FUERZAS

**19. Clasificación de las fuerzas. Fuerzas concurrentes, colineales, coplanas, y paralelas.** Se llaman concurrentes cuando sus direcciones se encuentran en un punto, como $a$, $b$, $c$, $d$, $e$, $f$, ó bien $f$ y $g$, fig. 8. No concurrentes,

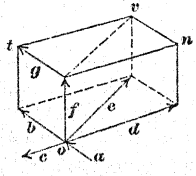

**Fig. 8.**

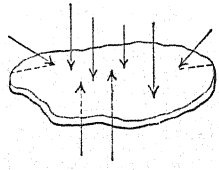

**Fig. 9.**

cuando no se encuentran así, como $c$ y $g$; colineales, cuando sus direcciones coinciden como $a$ y $b$, ó $c$ y $d$; no colineales, cuando no coinciden como $b$, y $f$; *coplanas* cuando sus direcciones están en un mismo * plano como $a$, $b$, $c$, $d$, $e$, ó bien $b$, $f$, y $g$; *no coplanas*, como $c$ y $g$, ó bien $b$, $f$, $d$, cuando están en planos diferentes; paralelas, cuando sus direcciones lo son, como $b$ y $g$; no paralelas, cuando no lo son sus direcciones, como $b$ y $f$.

Dos fuerzas paralelas cualesquiera están siempre en el mismo plano; tres ó más pueden estar ó no en el mismo plano. Dos fuerzas concurrentes están en un mismo plano, tres ó más pueden estar ó no. Dos fuerzas coplanas tienen que ser concurrentes ó paralelas.

---

* No debe confundirse obrar *contra* un plano (una fuerza, como en la fig. 9, á obrar *en* un plano, como en las figs. 70, etc.

## COMPOSICIÓN Y DESCOMPOSICIÓN DE LAS FUERZAS

**20. Resultante.** Cuando una sola fuerza puede producir sobre un cuerpo, considerado como un todo, el mismo efecto que dos ó más combinadas, se llama la resultante de ellas.

Así en la figura 10 (*b*) la presión hacia abajo, G = *w* + W es la resultante de las presiones hacia abajo *w* y W; y en la figura 11 (*b*) la presión hacia abajo = W — *w*, es la resultante de la presión hacia abajo W y del empuje hacia arriba de la cuerda del lado izquierdo.

**21. Componentes.** Dos ó más fuerzas que producen juntas, sobre un cuerpo considerado como un todo, el mismo efecto de una sola fuerza, se llaman **componentes** de dicha fuerza, y ésta es la resultante de aquéllas.

Así en la figura 10 (*b*) W y *w* son las componentes de la fuerza total, G = W + *w*. En la figura 11 (*b*), + W(= 5) y *w* (= — 3) son las componentes de G.

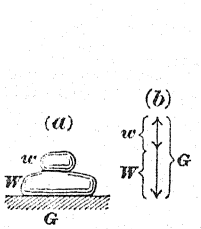

Fig. 10.

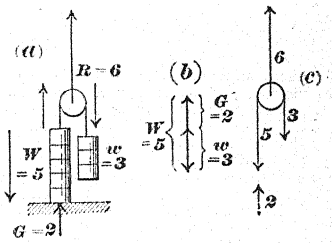

Fig. 11.

**22.** Cuando se considera la acción de la resultante de varias fuerzas, éstas (las componentes) dejan de considerarse, en lo que se refiere á su acción sobre el cuerpo como un todo, aun cuando se las tenga que apreciar por sus efectos sobre las partículas del cuerpo. Viceversa, consideradas las componentes, no se toma en cuenta la resultante.

**23. Antiresultante.** La antiresultante de una ó más fuerzas es una fuerza sola capaz de producir sobre cualquier cuerpo ó sistema de cuerpos considerado como un todo, el mismo efecto, pero en sentido contrario, que la resultante. En otras palabras : la antiresultante es la que destruye el efecto de las otras, manteniendo el equilibrio. Así, en la fig. 10 (*b*) la reacción del suelo hacia arriba G es la antiresultante de *w* y W obrando hacia abajo; y viceversa W + *w*, efecto hacia abajo, es la antiresultante de G. En la fig. 11 (*b*), G (obrando hacia arriba) es la antiresultante de W (hacia abajo) y *w* (obrando hacia arriba por intermedio de la cuerda izquierda). De modo análogo, el empuje hacia arriba de *w* es la antiresultante de W y G.

**24.** En cualquier grupo de fuerzas en equilibrio, una cualquiera de ellas es la antiresultante de las otras, y la resultante de dos ó más de ellas es la antiresultante de las demás. En tal sistema, la resultante y antiresultante de las fuerzas en equilibrio es cero.

**25. La anticomponente** de una fuerza ó de un sistema de fuerzas, son dos ó más fuerzas cuya resultante es la antiresultante de la fuerza ó sistema de fuerzas considerado.

**26. Composición y descomposición de las fuerzas.** La operación de encontrar la resultante de un sistema dado de fuerzas, se llama **composición** de fuerzas. Al contrario, encontrar las componentes de una fuerza dada, es la **descomposición** de la fuerza.

## Fuerzas colineales.

**27.** Supongamos que la línea vertical *w*, fig. 10 (*b*), representa, en una escala conveniente, el peso de la piedra superior en la fig. 10 (*a*) y W el de la piedra inferior. Entonces $w+W,=G,=$á la suma de las dos líneas, y dará, en la misma escala,

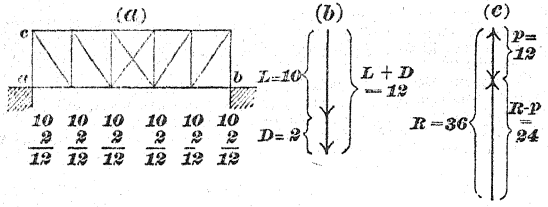

**Fig. 12.**

el peso combinado de las dos piedras, y la vertical G, que coincide con la línea de los pesos, $=$á su suma, y marcando su dirección hacia arriba, representará la anti-resultante, ó sea la reacción del suelo.

**28.** De modo análogo si en cada punto extremo de las secciones de la cuerda inferior de la armadura de un puente, fig. 12 (*a*), se supone una carga muerta de 2 toneladas (peso del puente, piso *, etc.), y 10 toneladas de carga viva (tren, vehículos, pasajeros, etc.), la longitud, sumadas las dos líneas, fig. 12 (*b*), dará L=10 y D=2, ó sea un total de peso, por sección, de 12 toneladas.

**29.** En la fig. 11, la presión de 5 kg de W sobre el suelo, está disminuída en 3 kg por el empuje hacia arriba del peso menor *w*, transmitido por la cuerda, y queda un residuo de dos kg de presión hacia arriba ejercido por el suelo, para mantener el equilibrio. La reacción hacia arriba R, de la polea es $=w+W-G=3+5-2=6$. Esto está gráficamente representado en la fig. 11 (*c*).

**30.** En la armadura de la fig. 12 (*a*) el total de las cargas muertas y móvil es $=6\times12=72$ toneladas, y la mitad móvil de este peso total (36 tons) descansa sobre cada estribo del puente. De aquí que, para conservar el quilibrio, cada estribo debe ejercer una reacción hacia arriba de 36 toneladas; pero, á fin de saber qué parte de las 36 toneladas se transmite por el *poste final, ac*, debemos deducir de ellas las doce toneladas que hemos calculado para la carga muerta y móvil, correspondiente al punto *a* de una sección, pues esta porción del peso es evidente que no se transmite por *ac*. Por tanto, en la fig. 12 (*c*), trazamos hacia arriba la línea R por escala $=36$ toneladas, y de su extremo superior hacia abajo trazamos $p=12$ toneladas. Lo que queda es $=R-p=36-12=24$ toneladas que es la presión transmitida por *ac*.

**31.** Las fuerzas colineales pueden estar en una misma ó en dirección contraria. Lo mismo sucede con las resultantes.

**Fig. 13.**

**32. Para que varias fuerzas colineales estén en equilibrio** se necesita que la suma de las fuerzas que obran en un sentido sea igual á la suma de las que obran en sentido opuesto, ó, de otro modo, que la suma algebraica de todas sea $=$cero.

Así, en la figura 13, si las fuerzas están en equilibrio, debe tenerse $ba+ao=ed+dc+co$; ó bien considerando las que obran hacia la derecha, *positivas*, y *negativas* las que obran hacia la izquierda, como se dijo en el § 10, debe tenerse :

$$b\ a+ao-oc-cd-de=0.$$

**33. Cuando dos fuerzas iguales y contrarias obran sobre un cuerpo,** se dice que lo mantienen en reposo; pero, hablando con exactitud, lo que hace cada fuerza es impedir que la otra lo mueva; mas no pueden evitar que otra ter-

* En realidad, la carga muerta no está nunca concentrada sobre una cuerda, como se indica aquí, pero por conveniencia suele suponérsela así.

cera, por pequeña que sea, y en cualquiera dirección que obre, lo ponga en movimiento. El cuerpo, por sí mismo, no tiende á moverse.

**34. Fuerzas desiguales opuestas.** Si dos fuerzas opuestas y desiguales obran sobre un cuerpo, la menor, y una parte de la mayor igual á ésta, obran en contra, sin producir efecto alguno sobre el cuerpo considerado como un todo, mientras que el residuo, ó sea la resultante, mueve el cuerpo en su propia dirección.

## Fuerzas coplanas concurrentes. Paralelogramo de las fuerzas.

**35. Composición.** Supongamos que las dos líneas *ao*, *bo*, en cualquiera de los dibujos de la fig. 14, representan en magnitud y dirección fuerzas concurrentes en el punto *o*. En el paralelogramo *acbo*, formado sobre las líneas *ao*, *bo*, la resultante de estas dos fuerzas está representada, en dirección y magnitud, por la diagonal R, que pasa por el punto *o*, donde concurren. El paralelogramo *acbo* se llama *paralelogramo de las fuerzas*.

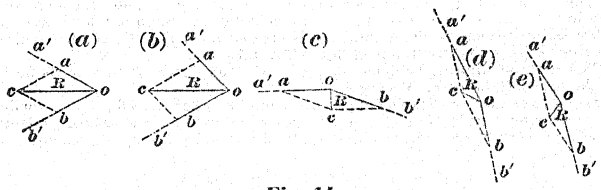

**Fig. 14.**

**36. Descomposición.** A la inversa, para encontrar las componentes de una fuerza dada *oc*, fig. 14, en dos direcciones dadas, *oa*, *ob*, trácese sobre esas direcciones las líneas *oa'*, *ob'*, y sobre éstas con la diagonal R=*oc*, constrúyase el paralelogramo de las fuerzas *abco*. Los lados *oa*, *ob* del paralelogramo que resulta representan las componentes en intensidad y dirección.

**37. Advertencia.** Las dos fuerzas *ao* y *bo*, fig. 14, pueden obrar las dos, ó empujando ó tirando del punto *o*, pero las líneas que las representan en el paralelogramo, y que se encuentran en *o*, deben ser trazadas lo mismo, y la resultante indicará una fuerza que empuja ó tira del punto *o*, según empujen ó tiren las componentes.

**38.** Así, en la fig. 15 (*a*), el poste final inclinado de la construcción empuja oblicuamente del punto *o* hacia abajo, con una fuerza representada por *a'o*, mientras el cordón inferior, tira de *o* hacia la derecha con una fuerza represen-

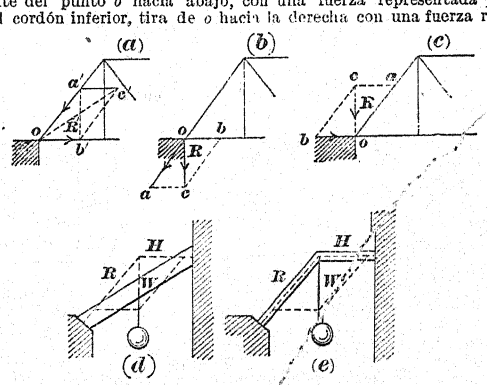

**Fig. 15.**

tada por *ob'*. Si construyésemos, como en la fig. 15 (*a*), el paralelogramo *oa'c'b'*, obtendríamos la diagonal *oc'* que no representa la verdadera resultante. Como

una de las fuerzas obra hacia el punto *o*, y la otra *desde* el punto *o*, no podríamos determinar en qué sentido estaría la flecha, aunque R' fuese la dirección de la resultante. Debemos suponer primero, que el empuje *a'o* en el poste extremo hacia *o*, pasa de *o* de manera que venga a obrar como una tensión *oa*, fig. 15 (*b*), quedando así ambas fuerzas consideradas como de tensión respecto al punto *o;* ó también podemos suponer que la tensión *ob'*, fig. 15 (*a*), de la cuerda se transforma en el empuje *bo*, fig. 15 (*c*), quedando consideradas ambas fuerzas como de empuje. En ambos casos se obtiene la verdadera resultante R (=*a'b'*, fig. 15 *a*); la cual, en este caso, representa la presión vertical hacia abajo del extremo de la construcción sobre el apoyo.

**Advertencia.** La fuerza de tensión, ejercida en un extremo de un tirante flexible, obra necesariamente en la dirección del tirante; pero, en general, la presión ejercida al extremo de un puntal sólo obra en la dirección del eje de aquél, cuando todas las fuerzas que la engendran están aplicadas al otro extremo. Así, en la figura 15 (*d*), las componentes R y H del peso, W, no coinciden con el eje de la viga que soporta la carga; pero en la fig. 15 (*e*), en donde el peso obra sobre la intersección de dos puntales, sus componentes R y H, sí coinciden con los ejes de éstos. (Véanse también figs. 143 y 145 *b*.)

**39. Demostración.** La demostración teórica del paralelogramo de las fuerzas se da en los tratados de Mecánica.

Se puede demostrar experimentalmente, como se indica en la fig. 16, en donde *co* representa por escala la tensión que marca el resorte C de la balanza, mientras que las fuerzas *oa*, *ob* están medidas por los resortes A y B respectivamente.

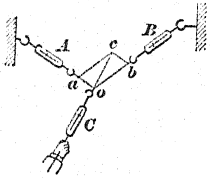

**Fig. 16.**

**40. Ecuaciones para las componentes y resultantes.** Dadas las intensidades de las fuerzas *a* y *c*, ó bien de la resultante R, y los ángulos por ellas formados, fig. 17 (*a*), tenemos * :

$$R = c\,\frac{\operatorname{sen}(x+y)}{\operatorname{sen} x} \quad = \quad a\,\frac{\operatorname{sen}(x+y)}{\operatorname{sen} y}$$

$$c = R\,\frac{\operatorname{sen} x}{\operatorname{sen}(x+y)}\,; \quad a = R\,\frac{\operatorname{sen} y}{\operatorname{sen}(x+y)}.$$

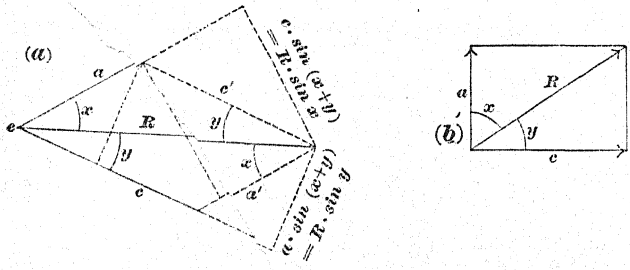

**Fig. 17.**

* Véase la línea de puntos, fig. 17 (*a*), y nótese que $c' = c \times \operatorname{sen}(x+y) = R.\ \operatorname{sen} x$; y $\operatorname{sen}(x+y) = R.\ \operatorname{sen} y$.

Si el ángulo entre las dos fuerzas es de 90°, fig. 17 (*b*) estas fórmulas se convierten en :

$$R = \frac{c}{\cos y} = \frac{a}{\cos x}; \qquad c = R \cos y; \qquad a = R \cos x.$$

**41. Posición y dirección de la resultante,** fig. 18. Si las líneas que representan las componentes se trazan de acuerdo con los §§ 37 y 38, y se traza una recta *mn*, ó bien *m'n'* por el punto *o* de aplicación, de modo que ambas fuerzas queden á un mismo lado de dicha línea, entonces la línea que representa la resultante queda del mismo lado que las componentes y entre ellas, y empujará ó tirará de la línea *mn* ó *m'n'* tal como lo hagan las componentes. La resultante está en el mismo plano que sus dos componentes.

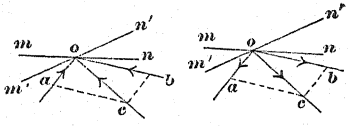

Fig. 18.

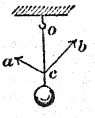

Fig. 19.

**42.** Si una de las componentes es colineal con la fuerza, entonces se confunden en una sola fuerza y puede considerarse la otra componente como *cero*. Es decir : una fuerza no puede descomponerse en dos fuerzas no colineales cuando una de ellas obra en la misma dirección de la fuerza. Así, la cuerda *oc*, fig. 19, puede recibir ayuda de *dos* cuerdas adicionales, que tiren según *ca* y *cb*, pues la resultante de sus tensiones puede coincidir con *co;* pero mientras *co* permanezca vertical, ninguna fuerza *sola* como *ca* ó *cb*, la puede reemplazar, á menos que actúe en su misma dirección *co*.

**43.** En la fig. 20, el peso P colocado en C está sostenido por completo por el miembro vertical BC, y no ejerce directamente ninguna tensión sobre el miembro horizontal CE. Ni tampoco ninguna tensión en este último ejercería efecto alguno sobre la fuerza que actúa en BC, mientras ésta permanezca vertical. Pero la tensión en BC, obrando en B, ejerce un empuje *oa* según BD, aun cuando ésta forma ángulo recto con BC. Como BC también encuentra allí la línea inclinada AB, la tensión *od* se descompone en *oa* y *ob* por BD y BA respectivamente.

El empuje horizontal *oa* en BD es en realidad la antiresultante de la componente horizontal *db*, del empuje oblicuo sobre el poste final BA, en su extremo B, cuyo empuje es=á la tensión en AE ejercida por P.

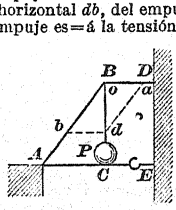

Fig. 20.

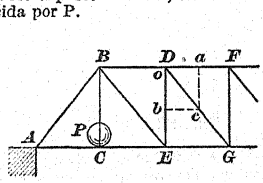

Fig. 21.

**44.** En la fig. 21, la tensión *oc* de la cuerda inclinada DG se descompone en D, en *oa* y *ob*, obrando una respecto á otra en ángulo recto, á lo largo de DF y DE respectivamente.

**45.** La resultante puede ser mayor ó menor que cualquiera de sus dos componentes oblicuas, pero siempre es menor que su suma. Si las componentes son iguales y el ángulo entre ellas es=120°, la resultante es=á una de ellas. Por tanto, con el peso que se rompe una cuerda vertical se rompen dos cuerdas iguales, formando cada una un ángulo de 60° con la vertical.

## Triángulo de las fuerzas.

**46. Triángulo de las fuerzas.** Como la diagonal de un paralelogramo lo divide en dos triángulos iguales, basta considerar uno de estos triángulos *aoc*, ó bien *boc*, figs. 14, 16, 18, en lugar de todo el paralelogramo.

**47.** Si tres fuerzas concurrentes, coplanas, se encuentran en equilibrio, las líneas que las representan formarán un triángulo, y las flechas que indican sus direcciones se siguen unas á otras alrededor del triángulo. Así, en la fig. 22 (*a*), tenemos, obrando en *o* y equilibradas, tres fuerzas, á saber : (1) la fuerza vertical hacia abajo *oc*, del peso, obrando como tensión por la cuerda *oc;* (2) el empuje horizontal *ao* por la viga *ao;* y (3) el empuje inclinado hacia arriba *bo* del puntal *ob*, las cuales obran en el sentido (*oc*, *ao*, *bo*), indicados por las flechas.

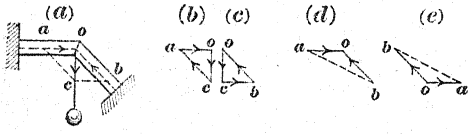

**Fig. 22.**

**48.** Cada una de las fuerzas de la fig. 22 (*b*) y (*c*) es la antiresultante de las otras dos del mismo triángulo, y si se invirtiese su dirección, se convertiría en la resultante. Así, *oc*, fig. 22 (*b*), es la antiresultante, y *co* la resultante de *ca* y *ao* : y *oc*, fig. 22 (*c*), es la antiresultante, y *co* la resultante de *cb* y *bo*, siendo *cb* paralela á *ao*, fig. (*b*), que representa el empuje ejercido por la viga horizontal en la unión *o*, fig. (*a*) *.

**49.** A la inversa, si los tres lados de un triángulo representan en dirección é intensidad tres fuerzas concurrentes, tales que las tres flechas que las representan, cada una en un lado, se siguen alrededor del triángulo, aquellas fuerzas estarán en equilibrio.

**50.** Las tres fuerzas, fig. 23, son respectivamente proporcionales á los senos de sus ángulos opuestos.

Así: fuerza *a* : fuerza *b* : fuerza *c*
= seno A · seno B : seno C.

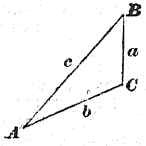

**Fig. 23.**

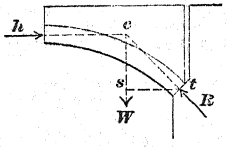

**Fig. 24.**

**51. Ej.** En la fig. 24, el semiarco y su riñón obrando como un solo cuerpo rígido, se presume que están en equilibrio por sus pesos combinados W, la presión horizontal *h* en la clave, y la reacción R del arranque oblicuo, la que se supone aplicada en su centro. En el triángulo de las fuerzas *cst*, obrando *cs* en el centro de gravedad del semiarco y su riñón representa el peso conocido W, y *st*, se traza horizontalmente, es decir, paralelo á la fuerza *h*.

En el punto *c*, donde la fuerza *h* prolongada encuentra la fuerza W, trácese *ct* por el centro del arranque, y entonces *st* y *ct* nos darán el valor de *h* y R respectivamente.

**52. Ej.** : Supongamos que la fig. 25 representa la armadura de un techo, que descansa en dos muros y que soporta tres pesos, indicados por las flechas. Trácese la vertical *a*R para representar los pesos cargados por el muro *a*, ó, lo que

---

* Fig. 22 (*d*) y (*e*), que representan las mismas dos fuerzas *ao* y *bo* de la fig. 22 (*a*) demuestra la resultante errónea (*ab*) que se obtiene si se trazan las fuerzas con sus flechas *hacia*, ó *del* punto de intersección de las líneas. (Véanse §§ 37 y 38.)

es lo mismo, la reacción vertical del apoyo hacia arriba. Luego trácese Rc paralela á *ad*, que es la cuerda de aquella parte de la armadura, hasta encontrar la arma-

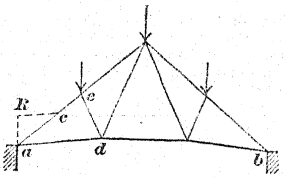

**Fig. 25.**

dura en *c*, y tendremos para los esfuerzos en *ae* y *ad* debidos á los tres pesos :

Esfuerzo en $ae = ac$

— $ad = Rc$.

**53.** Mientras que dos ó más fuerzas dadas como *ob* y *bc*, fig. 26 (*a*) (con sus flechas invertidas), ó bien *ob'* y *b'c*, ó bien *oa* y *ac*, ó bien *oa'* y *a'c*, pueden tener sólo

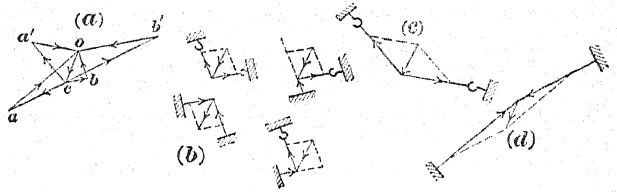

**Fig. 26.**

una resultante *oc;* una sola fuerza como *oc* puede descomponerse en dos ó más componentes, concurrentes en cualesquiera direcciones que se deseen. Es decir, que hay un infinito número de sistemas posibles de fuerzas concurrentes que tienen á *oc* por resultante.

## Componentes rectangulares.

**54.** Un ejemplo muy común de descomposición de fuerzas es aquel en que una fuerza, como la presión *cn*, del poste, fig. 27, se descompone en componentes que formen entre sí ángulo recto, como son las componentes vertical y horizontal *ct* y *tn* fig. 27 (*a*). Estas dos componentes, consideradas juntas, se llaman las componentes rectangulares de las fuerzas. El apoyo *od*, fig. 27 (*a*), se encuentra debidamente colocado perpendicular á *cn*, pero el apoyo *cib*. fig. 27 (*b*), prevé cualquier cambio accidental en la dirección *cn*. En la fig. 27 (*b*), las superficies *ci*, *ib*, deben trazarse, con preferencia, proporcionales respectivamente á las componentes *ct* y *tn*, fig. 27 (*a*), por la semejanza de los triángulos *cib* y *ctn*.

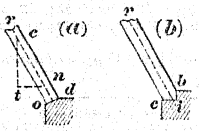

**Fig. 27.**

**55. Ej.** : En las armaduras de puentes y de techos, es preciso á menudo encontrar las componentes verticales y horizontales del esfuerzo en un elemento inclinado de aquéllas, es decir, determinar el esfuerzo que resulta sobre el elemento por la

acción de un esfuerzo vertical ú horizontal aplicado en uno de sus extremos en combinación con otro (cuya intensidad sea ó no conocida), y que obra en ángulo recto con aquél.

Así, en la fig. 28, la tensión *Cp*, en la diagonal *Cd*, se descompone en una presión *ep* á lo largo de la cuerda superior CD *, y en otra presión *Ce* sobre el poste *Ce* *. Agregándole á *Ce* el peso en *e*, y representando su suma por *fe*, tenemos la tensión *fg* en la parte de la cuerda *cd*, y la tensión *eg* en la diagonal *Be*. Haciendo *Bh*=*eg*,

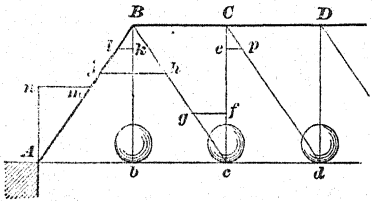

**Fig. 28.**

tenemos *jh*, compresión en BC; y *Bj*, compresión en el poste final inclinado BA. Pero la carga en *b* también transmite á B, por intermedio de la cuerda vertical *Bb*, una carga ó tensión igual á ella. Representando ésta por *Bk*, tenemos *lk* como su componente á lo largo de la porción de cuerda superior BC; y *Bl* como su componente á lo largo del poste final BA. Ahora, haciendo *Am*=á la suma de *Bj*+*Bl*, encontramos que la componente rectangular vertical es *An*=á la parte de la reacción vertical del apoyo que corresponde solamente á los tres pesos considerados, y la componente horizontal *mn*=al esfuerzo horizontal correspondiente á la parte *Ac* de la cuerda inferior.

**56. Ej. Plano inclinado.** Además, supongamos que en la fig. 29 se busquen las

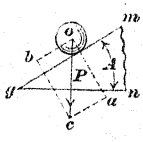

**Fig. 29.**

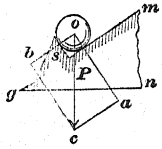

**Fig. 30.**

dos componentes rectangulares del peso P, respectivamente paralela y perpendicular al plano inclinado.

La primera es la tendencia del peso á rodar por el plano y se llama **componente tangencial**. La otra es la presión ejercida por el peso contra el plano y se llama **componente normal**.

Ahora sólo nos resta construir el triángulo de las fuerzas *oac*** trazando *oc*=P= peso del cuerpo; *oa* y *ac* en las direcciones requeridas. Entonces *oa* y *ac* dan respectivamente las componentes, normal y tangencial, de la fuerza P †.

**57.** Si suponemos que el plano inclinado *gm*, fig. 29, no produce fricción, y si al cuerpo *o* se le impide resbalar por él, empleado una fuerza aplicada paralela al plano, esta fuerza es=*ca*.

Así en la fig. 30, suponiendo que no haya fricción, tenemos *ac*= á la presión ejercida contra el obstáculo S.

---

* El esfuerzo encontrado, no es precisamente el *total* en el miembro. La compresión en *Ce* (despreciando su propio peso y el de la cuerda superior) se debe en su totalidad á la tensión *Cp* en *Cd* que obra en su parte superior, y de aquí que *Ce* represente la compresión total en *Ce;* pero *ep* es sólo *una parte* de la compresión soportada por CD, pues BC también contribuye.

** Ó bien *obc*. Si se trazan ambos triángulos tendremos el paralelogramo de las fuerzas *oacb*.

† La línea *ac* (ó bien *ca*) es la *proyección* de *oc* sobre el plano inclinado; y *oa* (ó bien *ao*) es la proyección de *oc* sobre *una normal* al plano inclinado.

**58.** Tabla de componentes normales y tangenciales para diferentes ángulos de inclinación:

| Inclinación del plano ó pendiente. La longitud de la pendiente = altura vertical / seno columna 4) | | | Presión sobre el plano dada en partes del peso ó coseno del ángulo del plano. | Fuerza de descenso en partes del peso, ó seno del ángulo del plano. |

**59. Ecuaciones.** En la fig. 29,

$$oa = P \times \cos\ c\ o\ a$$
$$ac = P \times \operatorname{sen}\ c\ o\ a$$

y siendo el ángulo *coa*, entre la vertical *oc* y la componente normal *oa* = ángulo A de la inclinación del plano *gm* con la horizontal *gn*, tenemos :

Componente normal $oa = P \cdot \cos A$.
Componente tangencial $ac = P \cdot \operatorname{sen} A$.

**60.** Cuando una fuerza se descompone en fuerzas rectangulares como en las figs. 29 y 30, cada componente representa el *esfuerzo total* ó *tendencia* que aquella fuerza sola ejerce *en dicha dirección*.

Así, en la fig. 31, el máximum de fuerza que sólo el peso *oc* puede ejercer perpendicularmente contra el plano, está representado por la componente *oa*, pues si para impedir que el cuerpo se deslice por el plano aplicamos una fuerza en otro

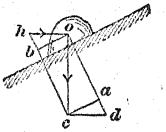

**Fig. 31.**

sentido, como por ejemplo la horizontal *ho*, en lugar de la tangencial *bo*, y encontramos las componentes de *oc* en las direcciones *ho*, *oa*, veremos que la componente normal *od* ha aumentado; pero el aumento *ad* se debe enteramente á la componente normal *hb*, de la fuerza horizontal *ho*. Así, el único efecto logrado sobre el cuerpo *o* y sobre el plano al sustituir *ho* por *bo*, es el de agregar la componente normal, *hb*, de la primera, á la componente normal (*oa*) de *oc*.

## Componentes.

**61. Componentes.** En la fig. 32 supongamos que *ao* y *bo* sean dos fuerzas cualesquiera y *co* su resultante. Desde *a* y *b* trácense *aa'* y *bb'* perpendiculares á la diagonal *oc* del paralelogramo de las fuerzas *aobc*, y constrúyanse los subparalelogramos (rectángulos) *oa'aa''* y *ob'bb''*. Cada una de las componentes originales *oa*, *ob*, quedan así descompuestas en dos subcomponentes, en ángulo recto, una de las cuales es también perpendicular á la resultante *oc*, mientras que la otra coincide con *oc* en posición y en dirección. Como las perpendiculares bajadas del vértice de los ángulos opuestos de un paralelogramo sobre su diagonal son iguales, resulta

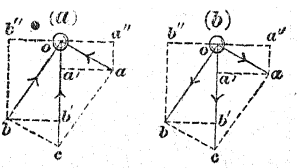

**Fig. 32.**

que las dos fuerzas colineales *oa''* y *ob''* son iguales y opuestas (aunque las líneas *a a* y *b'b* que las representan no son diametralmente opuestas; por tanto, están en equilibrio, y su único efecto sobre el cuerpo es de compresión en la fig. 32 (*a*), y de tensión en la fig. 32 (*b*). Las otras dos, *oa'* y *ob'*, se combinan para formar la resultante *oc*, que es igual á su suma, y que tiende á mover el cuerpo *o* en su dirección.

**62.** Las dos grandes fuerzas *oa*, *ob*, fig. 33 (*b*), tienen la misma resultante *oc* = *oc'* que las dos fuerzas pequeñas *oa'*, *ob'*, fig. 33 (*a*), aun cuando sus componentes $a''a = b''b$ son mucho mayores.

**63.** Sucede á menudo que una de las componentes es normal á la resultante. Así, en la fig. 22, donde *oc* es vertical, su componente *oa* es horizontal, y la perpendicular, tirada de *a* sobre *oc*, representa su anticomponente horizontal, *ao*. Aquí la viga horizontal y la inclinada soportan iguales presiones horizontales, por la presión vertical *oc*, = al peso W, está sostenida por la viga inclinada.

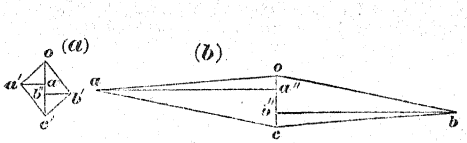

Fig. 33.

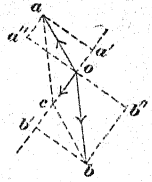

Fig. 34.

**64.** Cuando, como en la fig. 34, la resultante *oc* forma un ángulo *aoc* mayor de 90° con una de las componentes originales, las perpendiculares *aa'* y *bb'* de *a* y *b*, deben caer sobre la línea de la resultante prolongada. Aquí, sin embargo, como antes, las dos subcomponentes iguales y opuestas *oa''*, *ob''* están en equilibrio en *o*, mientras que las otras dos subcomponentes *ob'* y *oa'* van á formar la resultante *oc*, la cual, sin embargo (puesto que *ob'* y *oa'* obran aquí en sentido opuesto), es igual á su diferencia y no á su suma como en la fig. 32.

La fig. 34 demuestra que una fuerza *oc*, que obra hacia abajo, puede descomponerse de tal manera, que una de sus componentes *oa*, obrando *hacia arriba*, sea mayor que la fuerza original *hacia abajo*, y que la presión *ob* tenga una componente *ob'*, ó bien *b''b* paralela á *oc* y mayor que esta misma, pues $b''b = ob' = oc + cb'$.

## Aplicación de las fuerzas.

**65.** En la fig. 29, la bola está libre para correr por el plano, y aunque todo le peso P del cuerpo se aplica al plano *gmn*, sólo la *componente* normal *oa* obra sobre él ejerciendo una presión en la dirección *oa*. Pero, en la fig. 30, el plano *gmn* recibe y soporta no sólo la acción de la componente normal *oa*, sino también, por medio del obstáculo S, la componente tangencial *ob;* de manera que toda la fuerza P, ó bien, *oc*, obra sobre el plano *gmn* comprimiéndolo en la dirección *oc*.

## Composición y descomposición de las fuerzas concurrentes por medio de coordenadas.

**66.** Supongamos que, en la fig. 35 (*a*), las tres fuerzas coplanas E, F, G, obran en el punto *x*. Trácense dos líneas HH, VV en ángulo recto, cortándose en *o*, fig. 35 (*b*)*. Estas líneas se llaman coordenadas rectangulares. Desde el punto *o* trácense las líneas *o*E, *Fo* y *Go* paralelas á E*x*, F*x*, G*x* de la figura 35 (*a*) é iguales respectivamente á las fuerzas E, F y G usando una escala conveniente. Descompóngase cada una de estas fuerzas, fig. 35 (*b*), en dos componentes, paralelas á HH y VV respectivamente. Así *Eo* queda descompuesta en *to* y *no;* F*o*, en *ou* y *oe;* o*G*, en *oi* y *om*. Luego, sumando las componentes, tenemos

$$\text{Suma de las horizontales} = ou - oi - ot = -os,$$
$$\text{Suma de las verticales} = on + oe - om = oa;$$

y $-os$ y $oa$ serán las componentes de la resultante R de las tres fuerzas E, F y G.

**67.** Cuando un sistema de fuerzas concurrentes se encuentra en equilibrio, a suma algebraica** de las componentes de todas las fuerzas sobre cualquiera de las dos coordenadas, es cero.

Así, fig. 35 (*b*) ó 36, si la dirección de R es tal que venga á obrar como la antiresultante de las otras tres fuerzas E, F, G, sus componentes, *os* ó bien *oa*, sobre cualquiera de las coordenadas, compensará las de las otras fuerzas en la misma coordenada.

De aquí deducimos la importante proposición siguiente: cuando un sistema de

---

* Para más facilidad se trazan generalmente las coordenadas en ángulo recto, como en la fig. 35, mas se pueden hallar formando cualquier otro ángulo, como en la fig. 36; pero en todo caso las fuerzas deben, naturalmente, descomponerse en componentes *paralelas á las coordenadas*, cualquiera que sea la dirección de éstas.

** Las componentes se toman con signo + ó —, de acuerdo con la dirección de cada una.

fuerzas coplanas concurrentes está en equilibrio, las sumas algebraicas de sus componentes, en cualquiera de las dos direcciones, son iguales á cero.

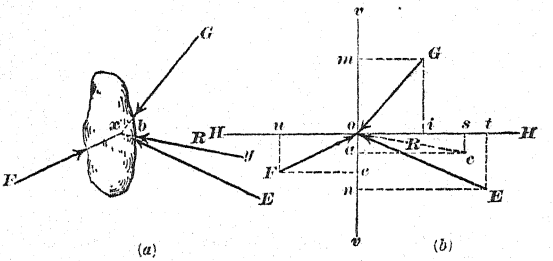

**Fig. 35.**

**68.** A la inversa, en un sistema de fuerzas concurrentes, si las sumas algebraicas de las componentes, en cualquiera de las dos direcciones, son iguales á cero, las fuerzas están en equilibrio.

Si la suma de las componentes en una cualquiera de las dos direcciones no es igual á cero, las fuerzas no pueden estar en equilibrio. Así, en la fig. 35 (*b*) ó 36 (*b*),

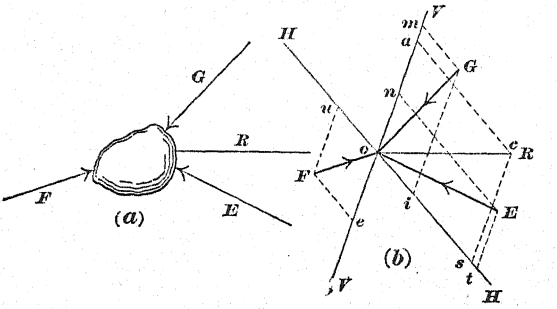

**Fig. 36.**

la suma de las componentes, á lo largo de una de las dos coordenadas (como VV), puede ser cero, y todavía si la suma de las fuerzas, á lo largo de la otra coordenada, no es cero, su resultante moverá el cuerpo sobre el que obran en la dirección de esa resultante.

**69.** Con coordenadas verticales y horizontales las condiciones de equilibrio * vienen á ser :

La suma de las componentes horizontales debe ser igual cero;
La suma de las componentes verticales debe ser igual cero;

ó más brevemente:

$$\Sigma \text{ componentes horizontales} = 0$$
$$\Sigma \text{ componentes verticales} = 0$$

A la inversa, si estas condiciones están satisfechas, las fuerzas están en equilibrio.

**70. Resultante de más de dos fuerzas coplanas.** Para encontrar la resultante de dos ó más fuerzas concurrentes coplanas como en la fig. 37, se encuentra primero la resultante $R_1$ de dos cualesquiera de ellas, como $P_1$ y $P_2$;

* Con fuerzas no concurrentes debe satisfacerse otra condición. (Véase § 83.)

entonces la resultante $R_2$ de $R_1$ y la tercera fuerza $P_3$; y así hasta obtener la resultante R de todas las fuerzas. Esta resultante es, evidentemente, concurrente y coplana de las fuerzas dadas.

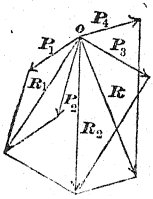

Fig. 37.

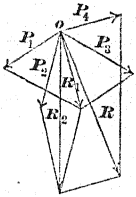

Fig. 38.

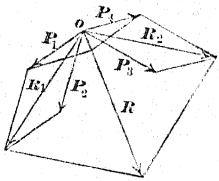

Fig. 39.

**71. El orden en que se van tomando las fuerzas** no tiene importancia. Así se puede componer primero, como en la fig. 38, la $P_1$ y la $P_2$, y entonces su resultante $R_1$ con $P_3$ obteniendo á $R_2$, y finalmente á $R_3$ con $P_4$ obteniendo R; ó, como en la fig. 39, se pueden combinar primero dos cualesquiera de las fuerzas como $P_1$ y $P_2$ obteniendo su resultante $R_1$; luego, procediendo con cualesquiera otras dos fuerzas como $P_3$ y $P_4$, obteniendo la resultante $R_2$, y finalmente combinando las dos resultantes $R_1$ y $R_2$ para obtener la resultante R.

## Polígono de las fuerzas.

**72. El polígono de las fuerzas.** Comparando las figs. 37 y 38 con las figs. 40 y 41, se ve que se puede llegar á la misma resultante R trazando simplemente, como en la fig. 41, líneas que representen las diversas fuerzas en cualquier orden, pero siguiéndose unas á otras, de acuerdo con su dirección. Adviértase que esto es solamente una abreviación del procedimiento de trazar los diversos paralelogramos de las fuerzas.

**73. Resultante y antiresultante.** La línea, — R, requerida para completar el polígono, representa la antiresultante de las otras fuerzas si su sentido es tal que las siga alrededor del polígono, como en la fig. 40. Si su dirección es opuesta á ellas, como en la fig. 41, entonces ella es su resultante R.

**74.** En otras palabras, si cualquier número de fuerzas concurrentes como $P_1$, $P_2$, $P_3$, $P_4$ y R, figs. 37 y 38 †, están en equilibrio, las líneas que las representan, trazadas en cualquier orden, pero de modo que en sus direcciones se sigan unas á otras, formarán un polígono cerrado, como en la fig. 40 (ó como en la fig. 41, si la dirección de R es contraria).

**75. A la inversa,** si las líneas que representan cualquier sistema de fuerzas concurrentes coplanas, cuando se las traza con su dirección, siguiéndose unas á

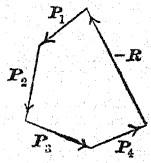

Fig. 40.

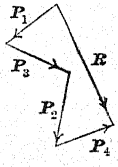

Fig. 41.

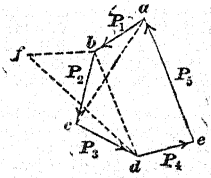

Fig. 42.

otras, forman un polígono cerrado, como en la fig. 40, esas fuerzas están en equilibrio.

Se observará que el triángulo de las fuerzas y la línea recta que representa un

† Aquí se considera que R obra hacia *arriba*, de manera de formar la antiresultante de las otras fuerzas.

sistema de fuerzas colineales, figs. 10 y 11, § 20, etc., ó un sistema de fuerzas paralelas, figs. 55, etc., § 111, etc., son simplemente casos especiales del polígono de las fuerzas.

**76.** En el polígono de las fuerzas, fig. 42, cualquiera de las fuerzas es la antiresultante de todas las demás. Dos ó más de cualquiera de las fuerzas equilibran á la demás, ó su resultante es la antiresultante de ellas.

Si se traza una línea *ac* ó *bd*, fig. 42, uniendo dos vértices cualesquiera de un polígono de fuerzas, esa línea representa la resultante ó la antiresultante (según vaya la flecha) de todas las fuerzas á cada lado de ellas; así:

| | | | | |
|---|---|---|---|---|
| *ac* es la resultante de | $P_1P_2$ | y la antiresultante de | $P_3P_4P_5$ | |
| *ca* | — | $P_1P_5P_4$ | — | $P_1P_3$ |
| *bd* | — | $P_2P_3$ | — | $P_1P_5P_4$ |
| *db* | — | $P_4P_5P_1$ | — | $P_2P_3$ |

**77.** Conociendo la *dirección* de *todas* las fuerzas de un sistema como $P_1 \ldots P_5$, fig. 42, y las intensidades de todas ellas, menos dos, como $P_2$ y $P_5$, podemos encontrar las intensidades de estas dos trazando primero las otras $P_4$, $P_5$ y $P_1$ como en la figura. Luego, dos líneas *bc* y *cd*, trazadas en las direcciones de las otras dos, y cerrando el polígono, darán sus intensidades.

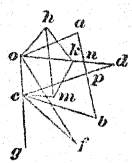

**Fig. 43.**

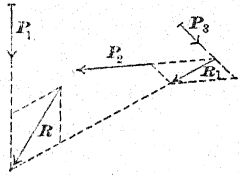

**Fig. 44.**

**78.** Si se toman dos puntos cualesquiera, como *o* y *c*, fig. 43, entonces la fuerza ó fuerzas representadas por cualquiera línea ó sistema de líneas que unan esos dos puntos, será equivalente á *oc*. Así, $oc = oabc = odc = onpc = ohkmc = ofc = ogc$, etc. Del mismo modo, en la fig. 42, el polígono de las fuerzas *abcdea* es equivalente al *abfdea* y al triángulo de las fuerzas *abca*, siendo cada cual = cero.

## Fuerzas coplanas no concurrentes.

**79. Fuerzas coplanas no concurrentes**, fig. 44. El procedimiento para encontrar la resultante de tres ó más fuerzas coplanas, pero no concurrentes, es el mismo que si fueran concurrentes. Así, supongamos que $P_1$, $P_2$ y $P_3$, representan tres de dichas fuerzas *. Puede encontrarse primero la resultante $R_1$ de dos cualesquiera de ellas, como $P_2$ y $P_3$; y luego, combinando $R_1$ con la fuerza restante $P_1$, se encuentra la resultante R de las tres. Aquí la línea R representa la resultante no sólo en intensidad y en dirección, sino también en posición. Es decir, la línea de acción de la resultante coincide con R.

**80. La resultante** R es la misma en intensidad y en dirección que si las fuerzas fueran concurrentes y tiene la misma posición que tendría si su punto de concurrencia estuviera en la línea de R. Para más de tres fuerzas se procede del mismo modo.

**81. Á la inversa**, la resultante R, ó cualquiera otra fuerza, puede descomponerse en un sistema de cualquier número de fuerzas coplanas, concurrentes ó no, en cualquiera dirección. Así podemos primero descomponer á R, en $P_1$ y $R_1$; luego á cualquiera de estas dos en otras dos fuerzas, como por ej.: $R_1$ en $P_2$ y $P_3$, etc.

**82.** Si un sistema de fuerzas coplanas no concurrentes está en equilibrio, permanecerán así situadas como si fueran concurrentes, con tal de que sus direcciones é intensidades no cambien; pero de aquí no se deduce que un sistema de fuerzas que está en equilibrio como concurrente, permanezca en equilibrio cuando esté colocado como no concurrente.

Así, las cinco fuerzas $P_1 \ldots P_5$, fig. 45 (*a*), pueden estar colocadas de tal manera

* Dos fuerzas coplanas, no paralelas, como $P_1$ y $P_2$ ó $P_2$ y $P_3$, son necesariamente concurrentes (véase § 19), pero pueden no concurrir en un solo punto las tres.

(como en la fig. 45 *b*), que la resultante *ac* de $P_1$ y $P_2$ no coincide con la resultante *ca* de $P_3$, $P_4$ y $P_5$, sino que le es paralela. Estas dos resultantes formarán entonces un par. (Véanse §§ 155, etc.)

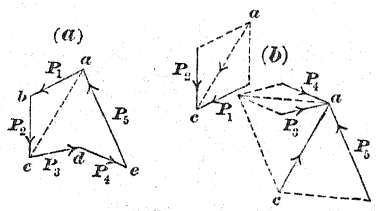

**Fig. 45.**

**83. Tercera condición de equilibrio.** De aquí que las condiciones de equilibrio para las fuerzas concurrentes, dichas en el § 69, son:

$$\Sigma \text{ de las componentes verticales} = 0$$
$$\Sigma \text{ de las componentes horizontales} = 0$$

no bastan para fuerzas no concurrentes, y debe agregarse una tercera condición, á saber:

$$\Sigma \text{ de los momentos} = 0;$$

es decir: los momentos de las fuerzas tomados con relación á cualquier punto deben estar en equilibrio.

Un sistema de fuerzas en equilibrio no tiene resultante; de aquí que no tiene momento con respecto á ningún punto. En otras palabras, los momentos de las fuerzas, así como las fuerzas mismas, están en equilibrio.

**84.** La resultante de un sistema de fuerzas no concurrentes ni en equilibrio, obrando sobre un cuerpo, puede ser:

(1) Una sola fuerza obrando por el centro de gravedad del cuerpo; ó

(2) Un par, es decir, dos fuerzas iguales, paralelas y contrarias (véanse § 155, etc.)

(3) O bien, (*a*) una sola fuerza obrando por el centro de gravedad del cuerpo, y un par; ó bien (*b*) una sola fuerza obrando fuera del centro de gravedad del cuerpo.

En el caso (3) las dos resultantes alternativas son cambiables entre sí; es decir, una sola fuerza obrando fuera del centro de gravedad del cuerpo, puede siempre ser reemplazada por una combinación equivalente, que consiste en una fuerza igual paralela, obrando por el centro de gravedad del cuerpo, y un par, y viceversa. (Véanse §§ 161, etc.)

La resultante en el caso (1) mueve el cuerpo en línea recta, sin rotación; en el caso (2) rotación sin traslación, y en el caso (3) ambos, traslación y rotación.

**85. Polígono de las fuerzas,** § 72, figs. 40, etc., y el método por coordenadas, § 66, fig. 35, nos dan por consiguiente solamente la intensidad, dirección y sentido de las fuerzas resultantes no concurrentes y *no* su posición. Para encontrar la posición de la resultante de fuerzas no concurrentes podemos recurrir á una figura como la fig. 44 en que las fuerzas están representadas en sus verdaderas posiciones; ó al polígono, §§ 86, etc., fig. 46.

## Polígono de cuerdas.

**86. En el triángulo de las fuerzas** dos cualesquiera de sus líneas pueden considerarse como representando las posiciones de dos miembros según sus direcciones (dos puntales ó dos cuerdas ó un puntal y una cuerda) de longitud indefinida y resistiendo á la tercera fuerza; al paso que sus longitudes dan las intensidades de las fuerzas que aquellos miembros deben ejercer para mantener el equilibrio.

**87.** Así, en la fig. 26 (*b*) tenemos cuatro diferentes sistemas de dos miembros cada uno, inclinados respectivamente como las fuerzas *cb* y *bo* en la fig. 26 (*a*) y equilibrando la tercera fuerza *oc*. Los miembros que obran como puntales están representados en la fig. 26 (*b*) como obrando contra superficies planas, al paso que los

que obran como cuerdas están representados como atados á ganchos de los cuales tiran.

En la fig. 26 (*c*) y (*d*) están indicados sistemas inclinados como las fuerzas *ca'*

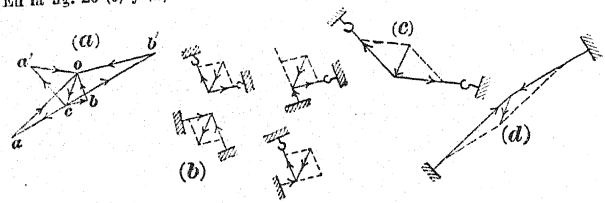

**Fig. 26 (repetida).**

y *a'o* y *ca* y *ao*, respectivamente, de la fig. 26 (*a*), por las cuales la tercera fuerza *oc* pudiera ser sostenida.

**88. En el polígono de la fuerza** *abcdea*, fig. 46 (*b*), que representa las cuatro fuerzas P P P P$_1$ de la fig. 46 (*a*), si escogemos á voluntad cualquier punto *o* (llamado **polo**) y trazamos desde él una serie de líneas rectas *oa*, *ob*, etc. (llamadas **radios polares**) hacia las extremidades *a*, *b*, *c*, etc., de las líneas P$_1$, P$_2$, etc., que representan las fuerzas, formaremos una serie de triángulos de fuerzas, *aob*, *boc*, etc. Así, en el triángulo *abo* tenemos la fuerza P$_1$, ó *ab*, equilibrada por las dos fuerzas *oa*, y *bo;* en el triángulo *bco*, la fuerza P$_2$, ó *bc* equilibrada por las dos fuerzas *ob* y *co;* y así de seguida.

**89. El polígono de cuerdas.** Si ahora, en la fig. 46 (*a*), tiramos las líneas *a* y *b*, paralelas respectivamente á los radios *oa* y *ob*, fig. 46 (*b*), que se encuentran en

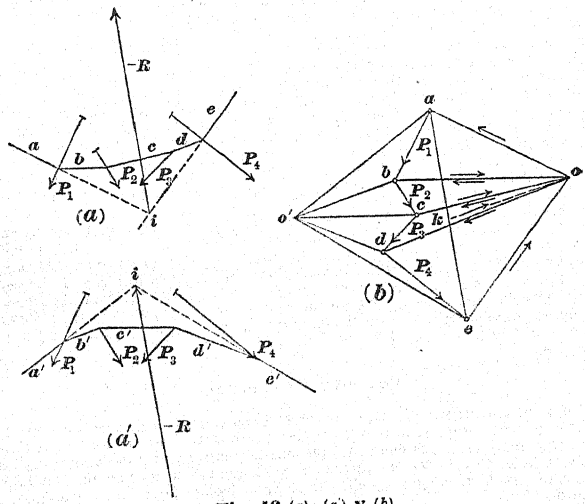

**Fig. 46** (*a*), (*a'*) **y** (*b*).

la línea que representa la fuerza P$_1$, aquéllas representarán las posiciones de las fuerzas de tensión de largo indefinido, que equilibrará la fuerza P$_1$, ejerciendo fuerzas representadas en intensidad y en dirección por los radios *oa* y *bo*, fig. 46 (*b*).

Del mismo modo, tomando el polo *o'*, fig. 46 (*b*), en vez de *o*, tenemos *a'* y *b'* fig. 46 (*a'*), paralelas respectivamente á los radios *o'a* y *o'b*, los que representarán un par de compresiones que hacen el mismo efecto.

**90.** Análogamente las líneas *b* y *c*, fig. 46 (*a*), paralelas respectivamente á los radios *ob* y *oc*, representan dos tensiones, las cuales, con fuerzas, ig uales respectivamente á *ob* y *co*, fig. 46 (*b*), equilibran la fuerza $P_2$.

**91.** Así obtenemos por fin un sistema de cinco fuerzas de tensión, *abcde*, fig. 46 (*a*), las cuales, si se las asegura debidamente en las extremidades *a* y *e*, equilibrarán, ejerciendo fuerzas representadas respectivamente por los radios *oa*, *ob*, *oc*, etc., fig. 46 (*b*), las cuatro fuerzas dadas $P_1$, $P_2$, $P_3$, $P_4$.

**92.** La figura *abcde*, fig. 46 (*a*), se llama *polígono de cuerdas, polígono funicular* ó *polígono de equilibrio*.

**93. Resultante, antiresultante. Intensidad y dirección.** En el polígono de las fuerzas, fig. 46 (*b*) ó (*d*), la línea *ea* que une el extremo de la última línea de fuerza *de* con el principio de la primera *ab*, se representa la antiresultante del sistema dado de cuatro fuerzas, y *ae* su resultante. Evidentemente pues, los rayos *ao* y *oe*, que representan dos componentes de *ae*, representan también, en dirección y en intensidad, dos fuerzas que equilibrarían á *ea*, ó que serían equivalentes al sistema dado de (cuatro) fuerzas.

**94. Posición de la resultante.** De aquí que, en el polígono de cuerdas, fig. 46 (*a*), la intersección *i* de las cuerdas *a* y *e*, paralelas respectivamente á los radios *oa* y *eo*, es un punto en la línea de acción de la resultante R; y si suponemos que *ai* y *ei* son piezas rígidas, y aplicamos en *i* una fuerza, —R, igual y paralela á *ae*, pero en dirección contraria, esa fuerza será la antiresultante de las (cuatro) fuerzas dadas, y tendremos un perímetro de cuerdas y piezas mantenido en equilibrio por las cinco fuerzas $P_1P_2P_3P_4$ y —R.

**95.** La elección del punto para situar el polo *o* en el polígono de las fuerzas, fig. 46 (*b*), no afecta á la resultante R; pero sí afecta á la forma del polígono funicular, fig. 46 (*a*) ó (*a'*). Así, con las fuerzas trazadas en el orden indicado en (*b*), y con el polo *á la derecha*, obtenemos, como en la fig. (*a*), una serie de fuerzas de

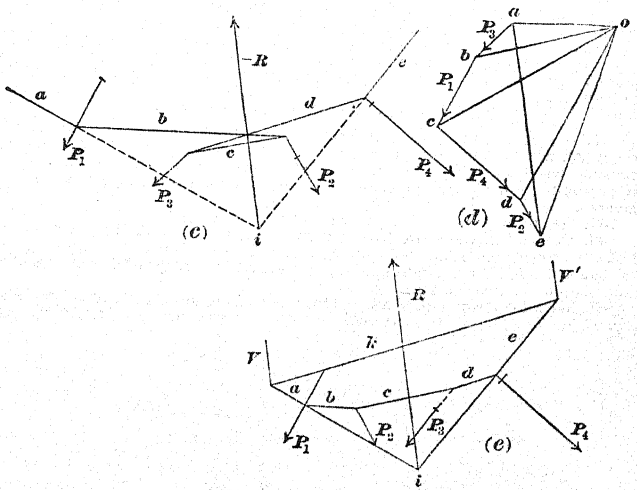

**Fig. 46** (*c*), (*d*) y (*e*).

tensión *a*, *b*, *c*, etc.; pero con el polo *á la izquierda* (fuerzas trazadas como antes) obtenemos una serie de fuerzas de compresión *a'*, *b'*, *c'*, etc. (fig. (*a'*).

**96.** Al construir el polígono funicular, fig. 46 (*a*), (*a'*), (*c*) y (*e*), debe tenerse

cuidado de trazar las fuerzas en sus correspondientes lugares; y para esto basta recordar que los dos radios pertenecientes á cualquiera línea de fuerza particular en el polígono de las fuerzas, fig. 46 (*b*), representan aquellos miembros que, en el polígono funicular, fig. 46 (*a*), toman las componentes de esa fuerza.

Así, *oa* y *bo*, fig. 46 (*b*), pertenecen á la fuerza $P_1$; *ob* y *co*, á la fuerza $P_2$. De aquí que, en la fig. 46 (*a*) ó (*c*), hagamos *a* y *b* (paralelas respectivamente á *oa* y *bo*) encontrarse en la línea de acción de $P_2$, etc.

**97.** Cada radio en el polígono de las fuerzas, fig. 46 (*b*), incluyendo los de afuera, se ven así pertenecer á dos fuerzas, y cada fuerza tiene dos radios. Las dos cuerdas paralelas respectivamente á los dos radios de cualquiera fuerza, deben ser trazadas de manera que se encuentren en la línea de la fuerza, y cada cuerda debe unir las líneas de acción de las dos fuerzas á que pertenezca su radio paralelo. Las líneas *a*, *b*, *c*, etc., en el polígono de cuerdas, fig. 46 (*a*) y (*c*), dan simplemente las *inclinaciones* de fuerzas que, de acuerdo con esa distribución, equilibrarían las fuerzas dadas. Las longitudes de estas líneas no tienen nada que hacer con las intensidades de las fuerzas. Éstas están dadas por las longitudes de los *radios* correspondientes en el polígono de las fuerzas, fig. 46 (*b*).

**98.** Si la antiresultante — R no está aplicada, puede suponerse que las cuerdas *a* y *e* estén fijadas á soportes firmes, contra los cuales ejercen fuerzas representadas, en intensidad y dirección, por los radios *ao* y *oe* respectivamente; pero es claro que las resistencias de aquellos dos soportes son iguales y opuestas respectivamente á *oa* y *eo*. De aquí que su resultante es la antiresultante — R de las cuatro fuerzas primitivas.

**99.** Si en la fig. 46 (*e*), las dos fuerzas extremas *a* y *e* estuvieran meramente sujetas á dos cuerdas, V y V', paralelas á la antiresultante — R, tirarían las extremidades de esas cuerdas para adentro, la una hacia la otra. Para impedir esto, colóquese el poste K con longitud tal, que las cuerdas V y V' permanezcan paralelas á —R, y trácese *ok*, fig. 46 (*b*), paralela á *k*. Entonces *ak* y *ke* representan las fuerzas en V y V' respectivamente.

**100.** Si la antiresultante — R, encontrada por medio del polígono de las fuerzas se aplica en una línea pasando por la intersección de los miembros exteriores (inicial y final) en el polígono funicular, todas las fuerzas, incluyendo por supuesto la antiresultante, estarán en equilibrio. En otras palabras, fuerzas coplanas están en equilibrio si se las puede trazar formando un polígono cerrado, y si se puede trazar entre ellas un polígono funicular. Pero si la antiresultante se aplica en otra parte, tendremos un par, compuesto de la antiresultante — R y de la resultante R de las fuerzas.

## Fuerzas concurrentes no coplanas.

**101.** Dos cualesquiera de las fuerzas concurrentes, como *oa* y *oc*, fig. 47 (*a*) e (*b*), son necesariamente coplanas. Encuéntrese su resultante *or*, que debe ser coplana con ellas y con una tercera fuerza *ob*. Entonces la resultante R, de *or* y *ob*, es la resultante de las tres fuerzas. Si hay otras fuerzas procédase de la misma manera.

**102.** Tres fuerzas no coplanas, concurrentes ó no, no pueden estar en equilibrio.

**103. Paralelepípedo de las fuerzas.** La resultante de tres fuerzas cualesquiera concurrentes, no coplanas, *oa*, *ob*, *oc*, fig. 47, estarán representadas por la diagonal *o*R, de un paralelepípedo, en el cual las tres aristas convergentes representan las tres fuerzas.

**104. Métodos por modelos. (a) Para tres fuerzas.** Constrúyase una caja, fig. 47 (*a*) ó (*b*), cuyas tres aristas convergentes representen las tres fuerzas en

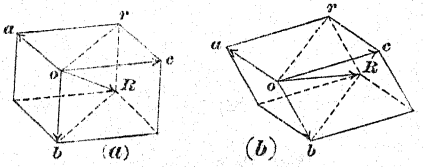

**Fig. 47.**

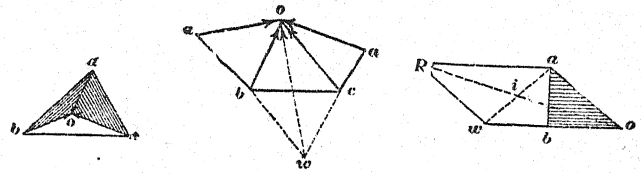
posición é intensidad. Entonces una cabulla *o*R que una los ángulos opuestos representa la resultante.

O bien, supongamos que las tres fuerzas *ao*, *bo*, *co*, fig. 48 (*a*), se encuentran en *o*. Trácense sobre un cartón las fuerzas *ao*, *bo*, *co*, como en la fig. 48 (*b*), con sus verdaderos ángulos *aob*, *boc*, *coa*, y encuéntrese la resultante *wo* de las dos del medio, *bo* y *co*. Córtese con nitidez toda la figura *aoacwba*. Háganse rayas profundas con un filo á lo largo de *ob*, *oc*, de manera que los dos triángulos exteriores puedan doblarse más fácilmente, en ángulos sobre el del medio, voltéense hasta que las dos aristas *oa*, *oa* se encuentren y luego péguese un pedacito de papel delgado á lo largo de la línea de unión para fijarlas. Párese el modelo sobre su lado *obwc* como base y ten-



(*a*) (*b*) (*c*)

**Fig. 48.**

dremos la forma de *chinela*, *aobw*, fig. 48 (*c*); siendo *ow* la suela y *aob* la cavidad para el pie. En el modelo la fuerza *ao* y la resultante *wo* de las otras dos fuerzas, se encuentran ahora en sus verdaderas posiciones relativas. Para encontrar su resultante córtese otro pedazo de cartón *Raow* con *Ra* y *Rw*, paralelas respectivamente á *wo* y *ao*. Trácese sobre cada lado de él la diagonal *Ro*, péguese este pedazo dentro del modelo con su arista inferior *wo* sobre la línea *wo*, fig. 48 (*b*), su arista *ao* en el ángulo *ao*. Hecho esto, *Ro* representa la resultante de *ao*, *bo*, *co*, fig. 48 (*a*), en su verdadera posición respecto á ellas.

**105. (b) Para cuatro fuerzas**, como *ao*, *bo*, *co*, *do*, en la fig. 49, se las traza, como en la fig. 49 (*a*), con sus ángulos *aob*, *boc*, etc. Trácense también las resultantes *vo*, de *co* y *bo*; y *wo* de *co* y *do*. Luego córtese toda la figura, como se hizo antes, y péguense las dos aristas *ao*, *ao*. Sosténgase el modelo de tal manera que dos de sus *planos* (como *aob* y *boc*) formen entre sí el mismo ángulo, como sucede con los dos planos correspondientes entre las fuerzas. Entonces tenemos las dos

(*a*) **Fig. 49.** (*b*)

resultantes *bo*, *wo*, fig. 49 (*b*), en sus *verdaderas relativas posiciones*. Córtese otro pedazo de cartón *Rvow*, fig. 49 (*b*), trácese la diagonal *Ro* de cada lado de él, y péguese dentro del modelo con *ov* y *ow*, sobre las líneas correspondientes del modelo. Luego *Ro* representará la resultante de las cuatro fuerzas *ao*, *bo*, *co*, *do* en su verdadera relativa posición respecto de ellas.

El modelo puede ser de madera, cortando separadamente los triángulos *aob*, *boc*, etc., biselando los filos de unión, y luego pegándolos con cola.

## Fuerzas no concurrentes y no coplanas.

**106. Fuerzas no concurrentes y no coplanas**, fig. 50 (*a*). (Para fuerzas paralelas no coplanas, véanse §§ 110, etc.) Descompóngase cada fuerza en dos rectangulares, una normal á un plano supuesto y la otra coincidiendo con el plano. Encuéntrese la resultante de las componentes (coplanas) que coinciden con el plano, por los métodos ya dados, y la de las componentes normales (paralelas) por los §§ 110, etc. Si estas dos resultantes son coplanas, serán también concu-

rrentes, y su resultante (que es la resultante de todo el sistema) se encuentra fácilmente.

**107.** Si no, supongamos que V, fig. 50 (*b*), sea la resultante normal al plano, y H, la resultante situada en el plano.

Por el § 162, sustitúyase la fuerza H por la H', igual y paralela, que encuentra

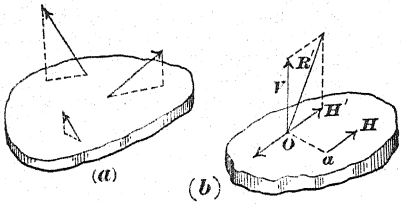


**Fig. 50.**

en O á V y el par $H \times Oa$; y búsquese la resultante R' de V y H'. El sistema de fuerzas queda así reducido á la única fuerza R' y al par $H \times Oa$. (Sobre pares, véase el § 155.)

**108. Momentos de fuerzas no coplanas.** La acción del peso W de la pared, fig. 51 (*a*), y de las fuerzas no coplanas $P_1$ $P_2$ pueden ser representadas, como en la fig. 51 (*b*), donde el eje *a'c'* representa la arista *ac* sobre la cual la pared tiende á girar, al paso que las perpendiculares de las fuerzas á la arista representan sus brazos de palanca. En cuanto a lo que se refiere á la estabilidad del muro, considerado como un cuerpo rígido y como capaz sólo de girar alrededor de la arista *ac*, no tiene importancia que una fuerza extraña como $P_1$ sea aplicada en *p* ó en *q*; pero sí tiene importancia si se considera la tendencia á hacer girar la pared horizontalmente, ó á romperla; ó en lo que se refiere á presiones (y fricciones con siguientes) entre el eje *a'c'* y sus puntos de apoyo.

Para el equilibrio $P_1 m = P_2 h + W \frac{b}{2}$. Aquí se ejerce en el eje una fuerza de torsión y se modifican más ó menos las presiones de sus extremidades en los puntos de apoyo; pero considerando sólo el equilibrio de los momentos, podemos suponer

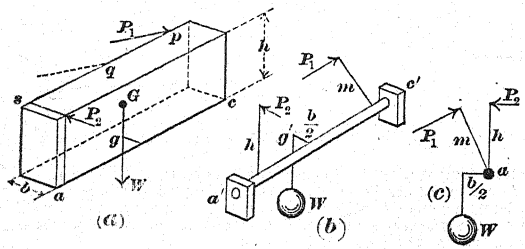

**Fig. 51.**

todas las fuerzas y sus momentos proyectados en el mismo plano, como en la fig. 51 (*c*).

**109.** En casos como el de la fig. 51, se acostumbra, por conveniencia, limitarnos á una supuesta sección vertical *s*, de un metro de grueso, y á considerar que las fuerzas obran sobre esa sección; suponiendo que el peso de la sección esté concentrado en su centro de gravedad y las fuerzas extrañas aplicadas en el mismo plano vertical del centro de gravedad. En efecto, así consideramos una sección indefinidamente delgada, pero cuyo peso es el de la sección de un metro.

## FUERZAS PARALELAS

**110. La resultante de cualquier número de fuerzas paralelas**, estén ó no en el mismo plano, y tengan ó no la misma dirección, es paralela á ellas y es = á su suma algebraica.

### Fuerzas paralelas coplanas.

**111. La resultante de cualquier número de fuerzas paralelas coplanas** está en el mismo plano que ellas, aunque las fuerzas sean del mismo sentido ó contrario; y los brazos de palanca de tales fuerzas y de su resultante, con respecto á cualquier punto del mismo plano, están en línea recta. Así, en la fig. 56 (*a*), donde las cinco fuerzas *a*, *b*, *c*, *d*, *e*, están en un plano, su resultante R está en ese mismo plano, y los brazos de palanca de las fuerzas y de R respecto á cualquier punto, como *b* ó *v*, del mismo plano, están en la línea recta R*v*.

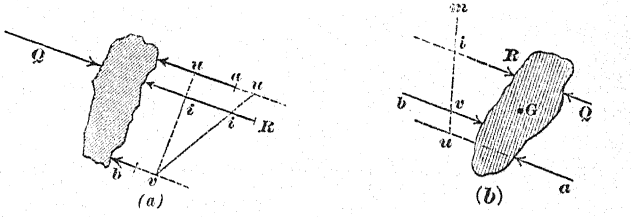

Fig. 52.

**112.** La resultante R ó la antiresultante Q, fig. 52, **de dos fuerzas paralelas** *a* y *b*, corta á cualquier línea recta, *uv*, que una las direcciones de las dos fuerzas; de aquí que, si tres fuerzas paralelas están en equilibrio, se hallan en el mismo plano. En la fig. 52 (*a*), las dos fuerzas *a* y *b* están en el mismo sentido. R está entonces entre *a* y *b*, y R = *b* + *a*. En la fig. 52 (*b*), *a* y *b* están en sentido opuesto. R no está entonces entre *a* y *b*, y R = *b* — *a*.

**113.** Para encontrar la posición de la resultante, trácese y mídase cualquier línea recta *uv*, uniendo las líneas de acción de las fuerzas. No importa que *uv* quede ó no perpendicular á dichas direcciones. La línea que representa la resultante corta á *uv* y su posición se encuentra así:

$$ui = uv \times \frac{b}{R}; \qquad \text{y } vi = uv \times \frac{a}{R}.$$

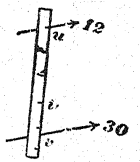

Fig. 53.

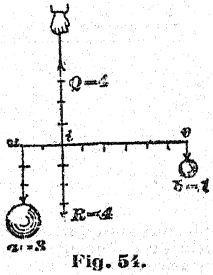

Fig. 54.

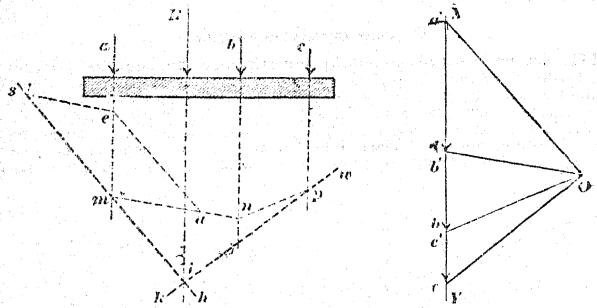
**114.** Esto se hace fácilmente trazando *uv* igual, en cualquier escala conveniente, á la suma de las fuerzas, como en la fig. 53, donde *uv* = 42. Luego hágase *ui igual*, por la misma escala, á la fuerza en *v*, ó *vi* = á la fuerza en *u*. Luego una línea R, fig. 52 (*a*), trazada por *i* paralela á *a* y b, da la posición y dirección de

su resultante, y su intensidad es=á la suma de $a$ y $b$; ó $R=a+b$. En otras palabras, si una fuerza Q, paralela á las fuerzas $a$ y $b$, é igual á su suma, pero en sentido contrario, se aplica al cuerpo en cualquier parte de una línea que pase por $i$, equilibrará á $a$ y $b$; será su antiresultante.



(a) **Fig. 55.** (b)

**115.** La posición de la resultante encontrada así, satisface la condición de equilibrio de los momentos; por tanto, $b \times vi - a \times ui = \text{cero}$. Si las dos fuerzas son iguales, su resultante R se encuentra evidentemente en el medio, entre ellas.

**116.** En la romana, fig. 54, las dos fuerzas $a$ y $b$ de la fig. 52 ($a$) están representadas por dos pesos, $a=3$ kg en $u$, y $b=1$ kg en $v$, con palancas $ui$ y $vi$ respectivamente, como 2 : 6 ó como 1 : 3.

Se observará en la fig. 56 ($a$) que la resultante R, debido á las posiciones é intensidades de las varias fuerzas, cae fuera del sistema de las fuerzas dadas.

**117.** Las figs. 55 hasta 58 ilustran la aplicación del polígono funicular (§§ 86 á 100) á las fuernas paralelas coplanas. Aquí el polígono de las fuerzas es, necesariamente, una línea recta.

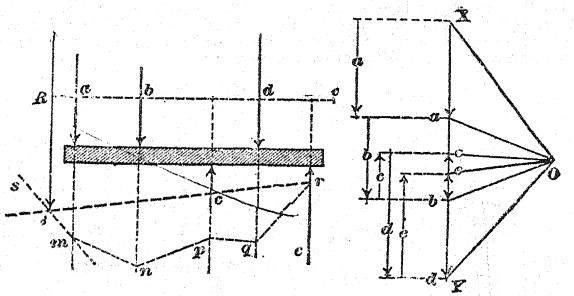


**Fig. 56.** (b)

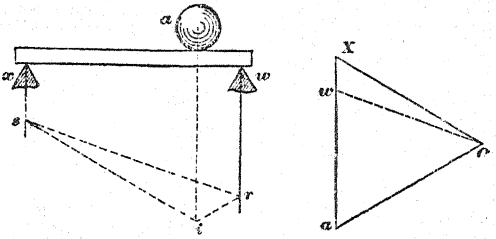
**118. Descomposición de las fuerzas.** Supongamos que la fig. 57 ($a$ **representa una viga que sostiene una sola carga concentrada,** $a$, situada fuera de su centro; y que se quiere encontrar la presión en cada uno de los dos apoyos $w$ y $x$.

Trácese X$a$, fig. 57 ($b$), representando la carga $a$ en escala, y radios XO, $a$O, á cualquier punto O fuera de la línea X$a$. En la fig. ($a$), de cualquier punto $i$ de la vertical por el punto $a$ donde está aplicada la carga, trácese $is$ e $ir$, paralelas respectivamente á OX y O$a$. Únase $rs$, y en la fig. ($b$) trácese O$w$ paralela á $rs$

Entonces los dos segmentos $wa$ y $Xw$, de $Xa$, dan por la escala las presiones sobre los dos soportes $w$ y $x$ respectivamente.



(a) **Fig. 57.** (b)

La mayor presión estará, por supuesto, sobre el soporte que queda más cerca de la carga; pero también sirve de guía recordar que el segmento adyacente á la línea radial OX, en la fig. (b), representa la presión sobre ese soporte $x$, fig. (a), que pertenece á la línea $is$ paralela á OX; y viceversa.

**119.** La fig. 58 representa un caso en que hay varias cargas sobre la viga. La intersección $i$, de las líneas $hs$ y $kr$, fig. (a), halladas respectivamente paralelas á OX y $c$O, fig. (b), muestra la posición de la resultante de las tres cargas. Aquí, como en la página 57, unimos $rs$, fig. (a), y trazamos O$w$, fig. (b), paralela á $rs$. Entonces $Xw$, fig. (b), da la presión en $x$, y $wc$ la de $w$.

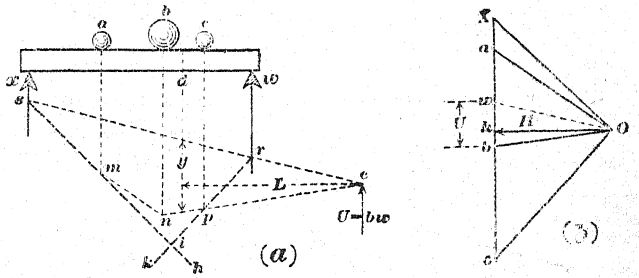


**Fig. 58.**

## Fuerzas paralelas no coplanas.

**120. Fuerzas paralelas no coplanas**, fig. 59 (a). Entre las líneas de acción de dos cualesquiera de las fuerzas, como $a$ y $b$, trácese cualquier línea recta $uv$, y se tendrá :

$$ui = uv \times \frac{b}{a+b}; \qquad vi = uv \times \frac{a}{a+b}.$$

Por $i$ trácese R′, paralela á $a$ y $b$, é igual á su suma. R′ es la resultante de $a$ y $b$. Entonces, de cualquier punto $i$, en la línea de acción de R′, trácese $iz$ á cualquier punto $z$ de la línea de acción de $c$, y hágase

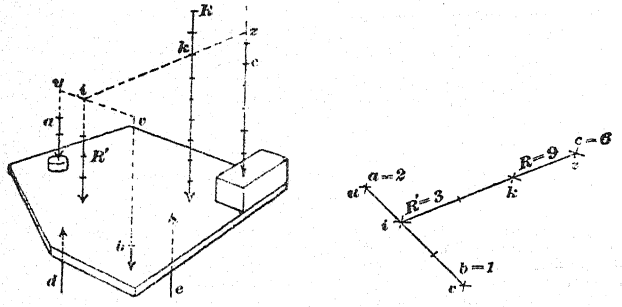
$$ik = iz \times \frac{c}{c+\mathrm{R}'}; \text{ ó } zk = iz \times \frac{\mathrm{R}}{c+\mathrm{R}'}.$$

Por $k$ trácese R paralela á $a$, $b$ y $c$, é igual á su suma y R será la resultante de $a$, $b$, $c$. Si hay otras fuerzas, procédase del mismo modo con ellas.

**121.** En la fig. 59 (a) colocamos á las fuerzas $a$ y $c$ obrando sobre superficies levantadas sobre el plano general, con el único objeto de demostrar que no es necesario que las fuerzas obren sobre una superficie plana.

**122.** También la fig. 59 (a) enseña el modo de encontrar la resultante de fuerzas

paralelas no coplanas, aunque no da todavía la verdadera posición relativa de las fuerzas y de su resultante, porque están dibujadas en una especie de perspectiva. y por tanto todas las partes no están sometidas á escala. La verdadera posición relativa puede, por supuesto, representarse en un plano, por las cinco cruceeitas $a$, $b$, $c$, $i$, $k$, fig. 59 ($b$), que corresponden á los puntos en que las fuerzas



(a)' **Fig. 59.** (b)

y la resultante cortan el plano supuesto. Pero ahora es imposible representar las fuerzas mismas por líneas; debe representárselas por números como se ha hecho aquí. Entonces es muy fácil encontrar, como antes, la posición de la resultante.

**123.** Si existen también fuerzas **que obran en dirección opuesta**, como $d$ y $e$, fig. 59 ($a$), encuéntrese su resultante separadamente.

Así se obtienen, finalmente, dos resultantes de sentido opuesto, Estas resultantes pueden ser iguales ó desiguales, colineales ó no. Si no son colineales, véase § 84, y *Pares*, §§ 155, etc.

**124. Método por proyecciones**, fig. 60. Encuéntrense, primero, las proyecciones $a'$, $b'$, $c'$ de las fuerzas $a$, $b$, $c$ sobre un plano cualquiera $xy$ paralelo á ellas, y luego sus proyecciones $a''$, $b''$, $c''$, sobre un segundo plano $xv$, paralelo á ellas y normal al primero. Encuéntrese la posición de la resultante R', de $a'$, $b'$, $c'$, en el plano $xy$ y la R'' de $a''$, $b''$, $c''$, en el plano $xv$. Ahora, como las líneas $a'$, $b'$ $c'$, y

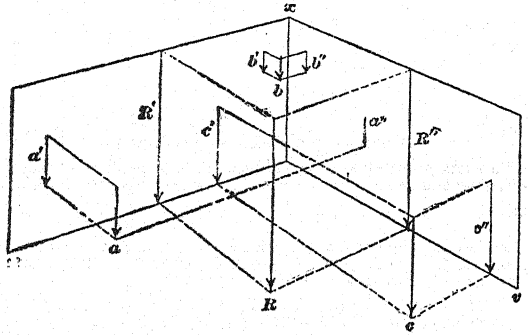


**Fig. 60.**

$a'$, $b''$, $c''$ son proyecciones de las fuerzas $a$, $b$, $c$, así R', R'' son proyecciones de la resultante R de las fuerzas. La posición de R está, por tanto, en la intersección de dos planos RR' y RR'' perpendiculares á los planos $xy$ y $xv$, y colocados sobre las proyecciones R', y R'', de la resultante R. $R=a+b+c$.

## CENTRO DE GRAVEDAD

**125.** Si un cuerpo, fig. 1 *, ó un sistema de cuerpos, fig. 2, se sostiene sucesivamente en diferentes posiciones, (*a*) y (*b*), la resultante de las fuerzas paralelas de la gravedad obrando sobre sus partículas, como lo indican las flechas en la figura, ocupará distintas posiciones con relación á la figura del cuerpo ó sistema. El punto donde todas aquellas líneas se encuentran, se llama el centro de gra-

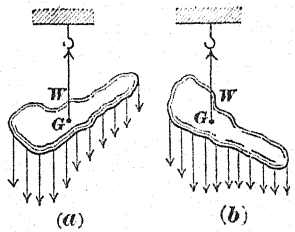

Fig. 1.

vedad del cuerpo ó sistema. Así, pues, si colocamos un cilindro recto homogéneo verticalmente sobre cualquiera de sus bases, la línea de gravedad coincidirá con el eje del cilindro; pero si luego se acuesta el cilindro sobre su lado, la vertical que pasa por el centro de gravedad dividirá al eje en dos partes iguales en ángulos rectos. De aquí que, en el cilindro, el centro de gravedad se encuentra en el centro del eje.

**126.** Respecto del centro de gravedad, todos los momentos debidos á la acción de la gravedad están en equilibrio, cualquiera que sea la posición del cuerpo ó sistema. De aquí que, si sobre el cuerpo ó sistema obra sólo la gravedad, y se los suspende por dicho centro, quedará en equilibrio; es decir, si está en reposo permanecerá así, ó si se le pone en movimiento, haciéndolo girar sobre su centro de gravedad, y luego se le deja, continuará girando indefinidamente, con velocidad angular uniforme. O si se le suspende libremente de cualquier punto, oscilará hasta que el centro de gravedad quede en reposo en la vertical del punto de suspensión.

**127.** En algunos cuerpos, tales como el cubo, ú otros paralelepípedos, la esfera, etc., el centro de *gravedad* es también el centro de la masa del cuerpo; pero con frecuencia no es así. En un cuerpo *ab*, fig. 2, por ejemplo, con su centro de gravedad en G, hay más masa (más peso) del lado *a*G que del lado G*b*.

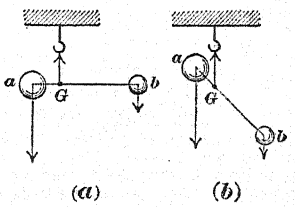

Fig. 2.

### Equilibrio estable, instable é indiferente.

**128.** Se dice que un cuerpo está en equilibrio estable cuando, como el péndulo, se le tiene suspendido de tal manera, que si se le mueve un poco hacia un lado,

* Las figs. 1 á 45 que se refieren al centro de gravedad están numeradas independientemente del resto de las series de figuras que se refieren á la Estática.

oscila hasta volver á su primitiva posición, es decir, con su centro de gravedad en la vertical y debajo del punto de suspensión.

**129.** Está en equilibrio instable, cuando, como en el caso de un huevo parado sobre su punta, se apoya de tal manera que si se le mueve sobre un lado y se le abandona, se separa de la vertical y cae.

**130.** Está en equilibrio indiferente, cuando, como sucede en una piedra de amolar sostenida por su eje horizontal, ó de una esfera que descansa sobre una mesa horizontal, está de tal modo suspendido ó apoyado, que si se le hace girar alrededor de su centro de gravedad y se le abandona, permanecerá en reposo ó con el movimiento angular transmitido.

## Reglas generales.

**131.** Las reglas generales que siguen, (1) á (6), forman la base de las reglas especiales, (7) á (39). Cuando hablamos del centro de gravedad de uno ó más cuerpos, suponemos para más facilidad que son homogéneos, es decir, de la misma densidad en todas sus partes y comparados unos con otros. El centro de *gravedad* es entonces el mismo que el centro de *figura*, y podemos usar los *volúmenes* en lugar de los *pesos*. Y, extendiendo esta regla á las **superficies** y líneas, usar las *áreas* de las superficies, y, en las *líneas*, sus *longitudes*.

En todas las reglas y figuras en que tratamos de esta materia, **G representa** el centro de gravedad, excepto cuando se establece otra cosa.

(1) **Dos cuerpos cualesquiera**, fig. 3, en los que se han encontrado los centros de gravedad, $g$, $g'$ de cada uno por medio de las reglas que se dan á continuación; **G** estará en la línea que une á $g$ con $g'$ y

$$g\mathbf{G} = gg' \times \frac{\text{peso en } g'}{\text{suma de los pesos } (g + g')}$$

$$g'\mathbf{G} = gg' \times \frac{\text{peso en } g}{\text{suma de los pesos } (g + g')}.$$

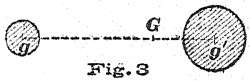

Fig. 3

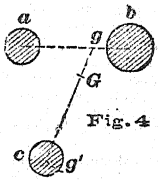

Fig. 4

(2) **Para cualquier número de cuerpos** como $a$, $b$, $c$, fig. 4, estén sus centros de gravedad en el mismo plano ó no, se procede así: Primero por la regla (1) búsquese el centro de gravedad $g$, de dos de ellos como $a$ y $b$. Entonces el centro de gravedad **G** de los tres cuerpos $a$, $b$, $c$ está en la línea $gg$ que une $g$ con el centro de gravedad $g'$ de $c$; y

$$g\mathbf{G} = gg' \times \frac{\text{peso de } c}{\text{suma de los pesos de } a,\ b,\ c};$$

$$g'\mathbf{G} = gg' \times \frac{\text{suma de los pesos de } a \text{ y } b}{\text{suma de los pesos de } a,\ b,\ c};$$

y así se sigue si hay otros cuerpos.

(3) En muchos casos un **cuerpo complejo** puede suponerse divido en partes cuyos varios centros de gravedad pueden encontrarse fácilmente.

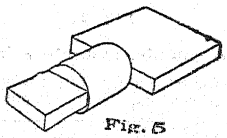

Fig. 5

Estonces el centro de gravedad del todo puede encontrarse por medio de las

reglas anteriores y las que siguen. Así, en el caso de la fig. 5 podemos encontrar separadamente los centros de gravedad de los dos paralelepípedos y del cilindro situado entre ellos, y en la fig. 6, los centros de gravedad del prisma cuadrado y la pirámide cuadrada (la última por medio de la regla (36); y entonces, conociendo en cualquiera de los dos casos los pesos de las diferentes partes se encuentra su centro común de gravedad como se ha indicado en las reglas (1) y (2).

Fig. 6

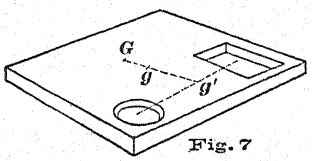

Fig. 7

(4) **Para cualquier cuerpo hueco,** ó que contiene uno ó más huecos, fig. 7, búsquese el centro de gravedad $g'$ de los huecos por medio de las reglas (1) ó (2), y el centro de gravedad $g$ de la figura entera como si no tuviera hueco. Entonces G está en la prolongación de la línea $gg'$, y

$$gG = gg' \times \frac{\text{suma de los volúmenes de los huecos}}{\text{volumen del cuerpo entero} - \text{volúmenes de los huecos}}$$

$$g'G = gg' \times \frac{\text{volumen del cuerpo entero}}{\text{volumen del cuerpo entero} - \text{volúmenes de los huecos}}.$$

**Advertencia.** Por conveniencia hemos mostrado los diferentes centros de gravedad $g$, $g'$, G, sobre la superficie de la figura. En el sólido real (que se supone que sea homogéneo) estarán en el centro de su espesor debajo de las posiciones indicadas en la figura.

(5) En cualquiera línea, figura ó cuerpo, ó en cualquier sistema de líneas, figuras ó cuerpos, cualquier plano que pase por el centro de gravedad se llama un « **plano de gravedad** » * para dicha línea ó sistema de líneas, etc. La intersección de dos planos de gravedad se llama « **línea de gravedad** ». El centro de gravedad es : (1.º) la intersección de dos líneas de gravedad; (2.º) la intersección de tres planos de gravedad, ó (3.º) la intersección de un plano de gravedad con una línea de gravedad que no está contenida en dicho plano.

Si una figura ó cuerpo tiene un eje ó plano de **simetría,** es decir (una línea ó plano que lo divida en dos partes equivalentes y semejantes), dicho eje ó plano es una línea ó plano de gravedad. Si una figura ó cuerpo homogéneo tiene un punto central, dicho punto es el centro de gravedad. (*N. del T.* — El texto dice así : « *Si una figura ó cuerpo tiene un punto central, dicho punto es el centro de gravedad* »; pero esto no es cierto sino cuando el cuerpo es homogéneo, por eso hemos agregado al traducir la frase *homogéneo* como condición.)

En la fig. 1, la cuerda representa una línea de gravedad y cualquier plano con el cual coincida la cuerda es un plano de gravedad. Así G puede encontrarse fácilmente, sobre todo en el caso de un cuerpo chato que permita colgarlo de una cuerda atada alternativamente por diferentes ángulos, ó sosteniéndolo en equilibrio en dos ó más posiciones sobre el filo de un cuchillo y buscando á G por medio de la intersección de las líneas ó planos de gravedad encontrados así.

(6) El '**método gráfico** de buscar la resultante de fuerzas paralelas puede usarse con ventaja para buscar el centro de gravedad de un cuerpo ó figura compuesta, ó de un sistema de cuerpos ó figuras cuando son conocidos los centros de gravedad de las diferentes partes.

Así, en la fig. 8, supongamos que $a$, $b$, $c$ representen tres figuras ó cuerpos cuyos centros de gravedad están en un plano. Trácense líneas verticales por dichos centros y fórmese el polígono de las fuerzas $xabc$, fig. 9, haciendo las líneas $xa$, $ab$, etc., proporcionales á los pesos de $a$, $b$, $c$; y trácense de cualquier punto conveniente O, líneas radiales $Ox$, $Oa$, etc. En la fig. 8 trácense $mh$, $mn$, $np$, $pk$, paralelas respec-

* *N. del T.* — No se usa en español esta frase ni la que sigue *línea de gravedad*, sin embargo las adoptamos porque son útiles y abrevian explicaciones.

tivamente á Ox, Oa, Ob, Oc. Entonces una línea vertical *i*G, trazada por la intersección *i*, de *mh* y *pk*, es una línea de gravedad del sistema ó figura. Si el cuerpo ó figura es *simétrico* como la sección transversal en forma de T de un carril ó de una viga en I, el eje de simetría que divide la figura en dos partes iguales y semejantes es también una línea de gravedad, y su intersección con la línea *i*G ya encontrada es el centro de gravedad G que se busca. En dichos casos es casi siempre más conveniente trazar las líneas á través de los diferentes centros de gravedad *perpendiculares* á los ejes de simetría, de modo que la línea de gravedad encontrada sea también perpendicular á ellos.

Pero si, como en la fig. 8, el cuerpo ó figura, etc., no es simétrico, debemos buscar una segunda línea de gravedad cuya intersección con la primera dé el centro de gravedad G. Para hacer esto repítase el procedimiento trazando otro juego de líneas paralelas á través de los diferentes centros de gravedad, fig. 8. Será más conveniente trazarlas horizontalmente ó en *ángulo recto* á las ya trazadas, como suponemos que se hace en las siguientes instrucciones.

Trácese entonces un segundo polígono funicular *m'n'p i'*, fig. 8, haciendo las líneas *m'n'*, etc., *perpendiculares* (en lugar de paralelas) á las líneas radiales Ox, etc., fig. 9; y trácese la segunda línea de gravedad *i'*G perpendicular á la primera. Entonces G está en la intersección de las dos líneas de gravedad.

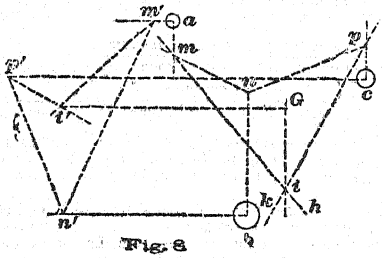

Fig. 8 Fig. 9

El dibujo del segundo polígono funicular es á menudo menos sencillo que el del primero, porque en el segundo las líneas paralelas á través de los diferentes centros de gravedad no se suceden necesariamente las unas á las otras en el mismo orden que en el primero. Debemos tener presente en este caso que las dos líneas (como *n'p'*, *n'm'*) que se encuentran en una línea paralela (como *bn'*), perteneciente á cualquier parte dada *b* de la figura, debe ser perpendicular respectivamente á las líneas radiales (*Oa*, *Ob*) que encuentran los extremos de la línea *ab* que representa esa misma parte.

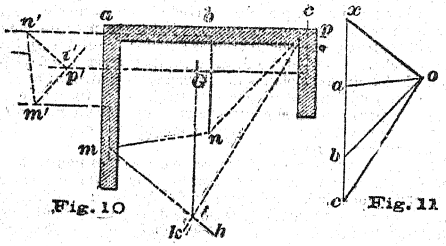

Fig. 10 Fig. 11

Las figs. 10 y 11 demuestran la aplicación del mismo procedimiento á una figura irregular compuesta de tres rectángulos *a*, *b*, *c*. Las letras son las mismas que

en las figs. 8 y 9; pero sucede en la fig. 10 que $i'$ y $p'$ del segundo polígono funicular cae sobre el mismo punto.

Si los centros de gravedad de varios cuerpos ó de varias partes del cuerpo, etc., están en más de un plano, debemos buscar sus proyecciones sobre determinados planos y aplicar el procedimiento á sus proyecciones.

## Casos particulares.

**132. Casos particulares** derivados de las reglas generales (1) á (6).

### Líneas.

(7) **En la línea recta**, G está en la línea y en el medio de su longitud.

(8) **Arco circular** * *aob*, figs. 12 y 13 (centro del círculo en *c*). G está en la línea *co* que une el centro del círculo con el medio del arco, y

$$cG = \text{radio } ac \times \frac{\text{cuerda } ab}{\text{longitud del arco } aob}.$$

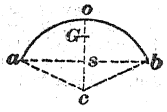

Fig. 12

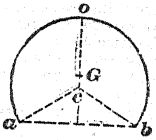

Fig. 13

(8*a*) Si el arco es una **semicircunferencia**, *

$$cG = \text{radio } ac \times \frac{2}{\pi} = \text{radio } ac \times .6366.$$

(8*b*) Reglas aproximadas para encontrar la distancia *s*G, fig. 12, de la cuerda al centro de gravedad.

| | | | | |
|---|---|---|---|---|
| Si la flecha | $so = .01$ | de la cuerda | $ab$; | $sG = .666 \times so$ |
| — | $= .10$ | — | — | $= .665 \times so$ |
| — | $= .15$ | — | — | $= .663 \times so$ |
| — | $= .20$ | — | — | $= .660 \times so$ |
| — | $= .25$ | — | — | $= .657 \times so$ |
| — | $= .30$ | — | — | $= .653 \times so$ |
| — | $= .35$ | — | — | $= .649 \times so$ |
| — | $= .40$ | — | — | $= .645 \times so$ |
| — | $= .45$ | — | — | $= .641 \times so$ |
| — | $= .50$ | — | — | $= .637 \times so$ |

(9) Para un **triángulo** *abc*, fig. 14, el centro de gravedad G de sus tres lados * es el centro del círculo inscrito en un triángulo, cuyos ángulos están en los centros de los lados del triángulo dado.

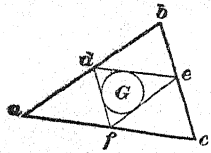

Fig. 14

(10) Para un **paralelogramo** (cuadrado, rectángulo, rombo ó romboide) el centro de gravedad de los cuatro lados * está en la intersección de las diagonales.

* Estamos tratando ahora solamente de líneas, no de las superficies encerradas por ellas. Respecto á superficies, véanse las Reglas (13), etc., etc.

(11) En el caso de un **círculo, elipse** ó **polígono regular**, el centro de gravedad de la circunferencia ó perímetro * es el centro de la figura.

(12) Para un **prisma regular** recto ú oblicuo y **pirámide regular** recta ó un **tronco de pirámide**, el centro de gravedad de sus aristas * es el centro de los ejes. En el *prisma* la posición de G no se afecta porque incluyamos ó no los lados de los dos polígonos que forman las bases.

(12*a*) **Cicloide** *. Véase pág. 204.

## Superficies.

### A. Superficies planas.

Tratemos ahora de los centros de gravedad de las *superficies* planas que pueden ser consideradas como cuerpos chatos infinitamente delgados. Las reglas para las superficies pueden también usarse para cuerpos chatos, no obstante que en éstos el centro de gravedad está en el medio del espesor inmediatamente bajo los puntos encontrados por las reglas establecidas para las superficies.

(13) **Paralelogramos** (cuadrado, rectángulo, rombo ó romboide), **círculo elipse** ó **polígono regular**. G está en el centro de la figura, ó en la intersección de dos diámetros cualesquiera, ó en el centro de cualquier diámetro. En un **paralelogramo**, G está en la intersección de las dos diagonales.

(14) **Triángulo**, fig. 15. G está en la intersección de líneas (como *ae* y *cd*) trazadas desde dos ángulos cualesquiera *a*, *c*, á los centros *e*, *d*, de los lados *bc*, *ab*, respectivamente opuestos á dichos ángulos. Dichas líneas se llaman « líneas medias ».

$$eG = {}^1/_3\, ae;\ dG = {}^1/_3\, cd;\ fG = {}^1/_3\, bf \text{ (siendo } f \text{ el centro de } ac).$$

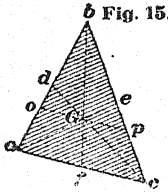

Fig. 15.

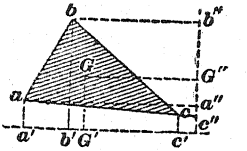

Fig. 16

(14*a*) Fig. 15. O en cualquiera de los dos lados (como *ab*), desde cualquier ángulo *a* hágase $ao = {}^1/_3\ ab$. Trácese *op* paralela al otro lado *ac*. Tómese $oG = {}^1/_2\ op$, y G estará en la intersección de *op* con cualquier línea media como *ae*, etc., etc.

(14*b*) Fig. 16. Si *aa'*, *bb'*, *cc'*, GG' son las distancias de los tres vértices y de G á cualquier línea recta ó plano *a'c'*, se tendrá que :

$$GG' = {}^1/_3\ (aa' + bb' + cc').$$

Esto nos da la posición de la línea de gravedad GG''. De la misma manera buscamos la distancia GG'' de G á cualquiera segunda línea ó plano *b''c''*. Esto nos da la posición de una segunda línea de gravedad GG' G está entonces en la intersección de GG' y GG'.

(14*c*) Fig. 17. La distancia G*n* de G á cualquier lado en cualquiera dirección

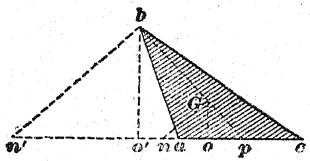

Fig. 17

como *ac* (prolongado si es necesario) es $= {}^1/_3$ de la distancia *n'b* medida en una dirección paralela desde el mismo lado al ángulo opuesto *b*.

* Véase nota página anterior.

Se deduce de esto que la distancia más *corta*, **G***o*, de **G** á cualquier lado (como *ac*) es $= {}^1/_3$ de la distancia más corta *o'b*, del mismo lado á su ángulo opuesto *b*.

Se deduce también que *p***G** es$={}^1/_3$ *pb* como en la Regla (14).

(**15**) **Trapecio ó trapezoide,** fig. 18. Para el trapezoide, véase también la Regla (16). Trácense las dos diagonales *ac*, *bd*. Divídase cualquiera de las dos como *ac*, en dos partes iguales, *am*, *cm*. Del punto *b* en *bd* hágase *bn*=*ds* (ó de *d* hágase *dn*=*bs*). Únanse *mn*. **G** estará en *mn*, y se tendrá

$$m\mathbf{G} = {}^1/_3\ mn.$$ (**G** es el centro de gravedad del triángulo *acn*.)

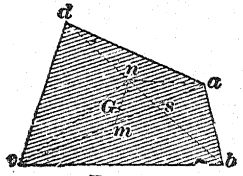

Fig. 18

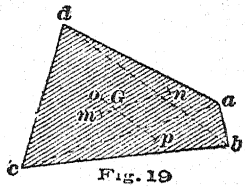

Fig. 19

(**15***a*) Fig. 19. O, de otro modo, búsquese primero los centros de gravedad *m* y *n* de los dos triángulos *cbd* y *abd* en los cuales está dividido el trapecio por una de sus diagonales *bd*. Únase *mn*. Búsquese los centros de gravedad *o* y *p* de los dos triángulos *dac* y *bac*, en los que está dividido el trapecio por su *otra* diagonal *ac*. Únase *op*. Entonces **G** estará en la intersección de *mn* con *op*.

(**16**) **Trapezoide solamente,** fig. 20. **G** está en la línea *ef* que une los centros *e*, *f* de los lados paralelos *ab*, *cd*. Para buscar su posición en dicha línea, prolónguese cualquiera de los lados paralelos, como *ab* en cualquiera dirección, digamos hacia *i*; y hágase *bi* igual al lado opuesto *cd*. Prolónguese entonces dicho lado opuesto *cd* en la dirección opuesta haciendo *dh*=*ab*. Únase *hi*. Entonces **G** estará en la intersección de *hi* con *ef*. Y se tendrá que

$$f\mathbf{G} = \frac{ef}{3} \times \frac{2ab + cd}{ab + cd};\quad \text{ó}\quad o\mathbf{G} = \frac{en}{3} \times \frac{2ab + cd}{ab + cd}.$$

Fig. 20

(**17**) **Polígonos regulares.** **G** es el *centro* de figura del polígono.

(**17***a*) **Polígonos irregulares.** Si el polígono se divide en dos partes cualesquiera, por cualquiera diagonal, **G** debe estar en la línea de gravedad que une los centros de gravedad de aquellas dos partes. Si dividimos otra vez el polígono entero en otras dos partes por otra diagonal, y unimos los centros de gravedad de esas dos partes, **G** estará en la intersección de las dos líneas de gravedad.

(**17***b*) O, de otro modo, podemos dividir el polígono en **triángulos buscando el** centro de gravedad de cada triángulo por medio de las Reglas (14), etc. y buscar entonces el centro **G** por la Regla general (1) (2) ó (6).

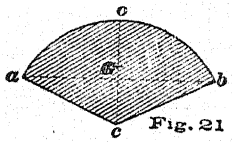

Fig. 21

(**18**) **Sector circular,** *aobc*, fig. 21. (Centro del círculo en *c*.)

$$c\mathbf{G} = \frac{2}{3}\text{radio } ac \times \frac{\text{cuerda } ab}{\text{arco } aob} = \frac{\text{radio}^2 \times \text{cuerda}}{3 \times \text{área}}.$$

Para encontrar la longitud del arco, véanse págs. 186, etc.

(18*a*) Si el sector es un **sextante** (sexta parte del círculo)

$$cG = \text{radio} \times \frac{2}{\pi} = \text{radio} \times .6366.$$

(18*b*) Si el sector es un **cuadrante**, fig. 22,

$$cG = \frac{4}{3}\,\text{radio} \times \frac{\sqrt{2}}{\pi} = \text{radio} \times .6002.$$

$$cx = xG = \frac{4}{3}\,\text{radio} \times \frac{1}{\pi}.$$

(18*c*) Si el sector es un **semicírculo**,

$$cG = \frac{4}{3}\,\text{radio} \times \frac{1}{\pi} = \text{radio} \times .4244$$

$$= \text{(aproximadamente) radio} \times \frac{14}{33}.$$

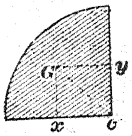

Fig. 22

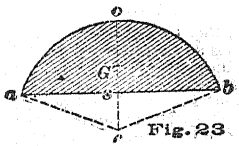

Fig. 23

(19) **Segmento circular**, *aobs*, fig. 23. (Centro de círculo en *c*.)

$$cG = \frac{\text{cubo de la cuerda } ab}{12 \times \text{área del segmento}}.$$

(19*a*) Si el segmento es un **semicírculo**,

$$cG = \frac{4}{3}\,\text{radio} \times \frac{1}{\pi} = \text{radio} \times .4244$$

$$= \text{(aproximadamente) radio} \times \frac{14}{33}.$$

(20) **Cicloide**, fig. 24. (Con el vértice en *v*.)

$$vG = \frac{7}{12}\,vl.$$

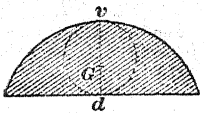

Fig. 24

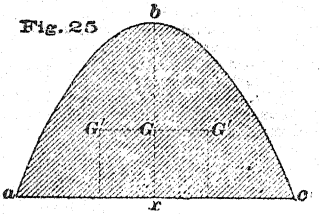
Fig. 25



(21) **Parábola**, *abc*, fig. 25. *ac* es a base; *ax*, *cx*, ordenadas; y la altura ó eje *bx*, abscisa. Centro de gravedad en **G**, en el eje *xb*, y

$$xG = \frac{2}{5}\,xb.$$

(21*a*) **Semiparábola**, *abx* ó *cbx*. Centro de gravedad en **G'**; y

$$xG = \frac{2}{5}\,xb; \quad GG' = \frac{3}{8}\,ax = \frac{3}{8}\,cx.$$

(22) **Elipse,** *mnop*, fig. 26. El centro de gravedad, *c*, de toda la elipse, está en el centro de la figura.

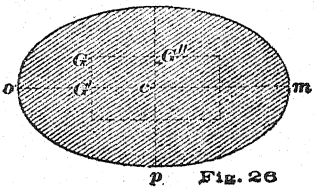


Fig. 26

**G** es el centro de gravedad de la cuarta parte de la elipse, *onc.*
**G'** — — mitad — *nop.*
**G'** — — — — *mno.*

$$cG' = \frac{4}{3}\,oc \times \frac{1}{\pi} = .4244\,oc = \text{(aproximadamente)}\ \frac{14}{33} \times oc.$$

$$cG = G'G = \frac{4}{3}\,cn \times \frac{1}{\pi} = .4244\ cn = \text{(aproximadamente)}\ \frac{14}{33}\,cn.$$

(23) **Para cualquier figura plana,** trácese la figura por escala en cartón grueso. Córtese y equilíbrese el cartón en dos ó más posiciones sobre la orilla de una mesa ó en el filo de un cuchillo; márquese en ella las diferentes posiciones de las líneas de sostén. Donde se intersecten éstas es el centro de gravedad. Se necesita, por supuesto, mucho cuidado para obtener resultados muy exactos por medio de este método. Antes de balancear el cartón, sus bordes superiores deben ser divididos en pequeñas partes iguales. De otra manera sería difícil fijar las posiciones de las líneas de sostén. El papel sobre el cual se prepara la figura debe ser suficientemente rígido para que la figura no se doble cuando se la sostiene en el filo del cuchillo. Véase Regla (5).

## B. Superficies de sólidos *.

(24) En la superficie curva * de la **esfera** ó **esferoide** (ó **elipsoide**), **G** está en el centro de la figura.

(25) En la superficie curva * de cualquier **zona esférica,** ó **segmento esférico, hemisferio,** etc., fig. 27, **G** es el centro del eje ó altura, *ao* †.

En el **hemisferio** $oG = \frac{1}{2}$ radio †.

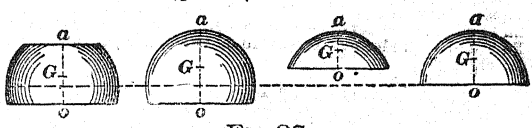

Fig. 27

(26) En el **prisma** recto ú oblicuo cuyos extremos son ó figuras regulares, ó paralelogramos (esto incluye el **cubo** y otros **paralelepípedos**); y en el **cilindro** recto ú oblicuo (circular ó elíptico), el centro **G** de la *superficie* * (incluyendo ó excluyendo ambos de los dos extremos paralelos) es el centro del eje ó línea que une los centros de los dos extremos paralelos.

(27) En la superficie curva *† de un **cono** recto, fig. 28 (circular ó elíptico) ó en las superficies *† inclinadas de **pirámides** rectas regulares, fig. 29, **G** está en el eje *oa* (línea que une el vértice con el centro de la base); y

$$oG = {}^1/_3\ oa.$$

En un cono *oblicuo* ó pirámide, la distancia perpendicular de **G** * contada desde

---

★ Tratamos ahora de las *superficies* de los sólidos y no de sus volúmenes. Para éstos, véanse las Reglas (29), etc.

† Si se han de incluir las **bases**, véanse las Reglas (1) y (2).

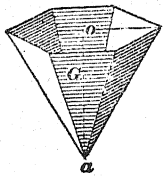

Fig. 29

la base es una tercera parte de la altura perpendicular como en el cono recto y pirámide; *pero no está en los ejes.*

(28) Superficies de troncos de pirámides y conos, de bases paralelas, figs. 30 y 31. En las superficies *+ curvas de los troncos de conos rectos (circulares ó elípticos), ó superficies *+ inclinadas de troncos de pirámides regulares rectas, G está en el eje *oa* (línea que une los centros de las dos bases paralelas), y

$$oG = \frac{1}{3}\,oa \times \frac{\text{circunferencia de } o + 2 \text{ circunferencia de } a}{\text{circunferencia de } o + \text{circunferencia de } a}.$$

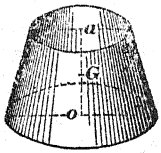

Fig. 30

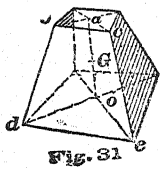

Fig. 31

En el **cono truncado**, fig. 30, podemos usar del *radio* de las dos bases; y en un **tronco de pirámide regular**, fig. 31, cualquier *lado* de las bases (como *be* y *de*) en lugar de las circunferencias.

## Sólidos.

En las Reglas siguientes para determinar el centro de gravedad de los sólidos, el sólido se supone *homógeneo*, es decir, de densidad uniforme en todas sus partes, de modo que el *centro de gravedad* es el *centro de figura.*

(29) En la **esfera** y **esferoide** (ó **elipsoide**), G es el centro del cuerpo.

(30) En el **hemisferio**, fig. 32. (Centro de esfera en *c*.) Altura $cT$ = radio $cb$. G está en el eje $cT$, y

$$cG = \frac{3}{8}\,cT = \frac{3}{8}\,\text{radio } cb.$$

(31) En el **sector esférico**, fig. 33. (Centro de esfera en *c*.)

$$cG = \frac{3}{4}\left(\text{radio } cb - \frac{h}{2}\right).$$

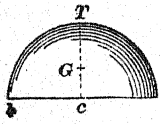

Fig. 32.

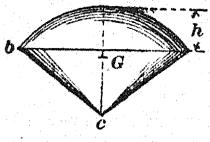

Fig. 33.

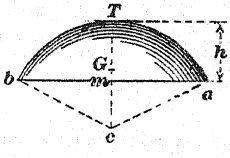

Fig. 34.

*+ Véanse estas notas al pie de la página anterior.

(32) **Segmento esférico** *amb*T, fig. 34. Centro de esfera en *c*. Centro de la base en *m*. Altura del segmento ó flecha $= mT = h$. G está en el eje *m*T, y

$$cG = \frac{3}{4} \times \frac{(2 \text{ radios } cb \text{ de la esfera} - \text{altura}, h)^2}{3 \text{ radios } cb \text{ de la esfera} - \text{altura}, h}$$

$$mG = \frac{\text{altura}, h}{2} \times \frac{2 (\text{radios } mb \text{ de la base})^2 + (\text{altura}, h)^2}{3 (\text{radios } mb \text{ de la base})^2 + (\text{altura}, h)^2}$$

$$= \frac{\text{altura}, h}{4} \times \frac{4 \times \text{radio } cb \text{ de la esfera} - \text{altura}, h}{3 \times \text{radio } cb \text{ de la esfera} - \text{altura}, h}.$$

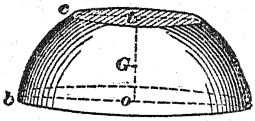

Fig. 35

(33) **Zona esférica**, fig. 35.

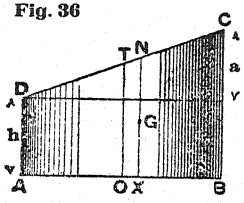
$$oG = \frac{ot}{2} \times \frac{2 (\text{radio } ob \text{ de la base inferior})^2 + 4 (\text{radio } te \text{ de la base sup})^2 + (\text{altura}, ot)^2}{3 \text{ radio } ob \text{ de la base inf})^2 + 3 (\text{radio } te \text{ de la base sup})^2 + (\text{altura}, ot)^2}$$

(34) **Prismas** regulares ó irregulares, rectos ú oblicuos (incluyendo el **cubo** y otros **paralelepípedos**, y **cilindros** circulares ó elípticos, etc., regulares ó irregulares, rectos ú oblicuos. G es el centro de los ejes que une los centros de gravedad de las dos bases.

(34*a*) En un cilindro ó prisma de muy **poca altura**, tal como una plancha de hierro, etc., búsquese el centro de gravedad de su *superficie*. El centro de gravedad del cuerpo está en el medio de su espesor, debajo del punto encontrado.

(35) **Uña de un cilindro**, circular ó elíptico (cuando uno de los ejes de la elipse coincide con el plano secante oblicuo), recto ú oblicuo, figs. 36 y 37.

Fig. 36



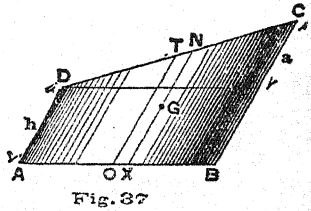


Fig. 37

Sea OT el eje (que une los centros de gravedad de las bases), y XN una línea trazada paralela al eje en el plano ABCD, que pasa por el eje y por los puntos superiores é inferiores C y D del plano secante oblicuo. La posición de G en el plano ABCD se encuentra así :

$$OX = \frac{OB}{4} \times \frac{a}{2h + a};$$

$$XG = \frac{XN}{2} = \frac{1}{4}\left(2h + a + \frac{1}{4}\frac{a^2}{2h + a}\right).$$

(35*a*) Figs. 38 y 39. Si el plano oblicuo CD *encuentra* la base AB, en A, del modo que $h = 0$, mientras CD permanece siendo una elipse ó círculo completo, éstas se transforman en

$$OX = \frac{OB}{4}; \quad XG = \frac{XN}{2} = \frac{5}{16}a.$$

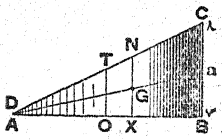

Fig. 38

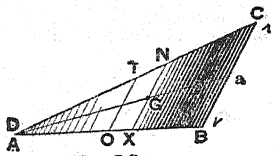

Fig. 39

(36) **Conos**, figs. 40 y 41, circulares, elípticos, etc., rectos ú oblicuos; ó **pirámides**, regulares ó irregulares, rectas ú oblicuas. El centro de gravedad G está en el eje OT, trazado del vértice T al centro de gravedad O de la base, y

$$OG = \frac{OT}{4}.$$

Fig. 40

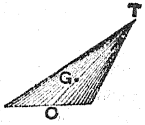

Fig. 41

(37) **Tronco de cono**, figs. 42 y 43, circular ó elíptico, recto ú oblicuo ó **tronco de pirámide**, regular ó irregular, recta ú oblicua; de bases AB, CD paralelas.

Llámese el área de la base grande A, y el de la pequeña *a;* y *h* la altura OZ del tronco, *medido á lo largo de su eje.* Entonces

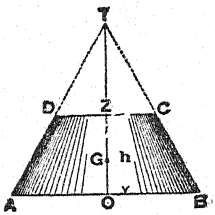

Fig. 42

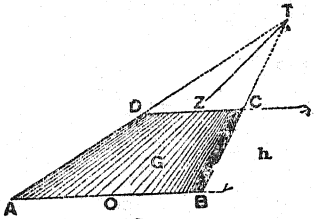

Fig. 43

G está en el eje OZ que une los centros de gravedad O y Z de las dos bases; y su distancia desde la base AB, medida á lo largo del eje,

$$OG = \frac{h}{4} \times \frac{A + 2\sqrt{Aa} + 3a}{A + \sqrt{Aa} + a}.$$

(37*a*) En un *tronco de cono circular*, recto ú oblicuo, de bases paralelas, tenemos:

$$OG = \frac{h}{4} \times \frac{R^2 + 2Rr + 3r^2}{R^2 + Rr + r^2},$$

en que R y *r* son los radios de las bases inferior y superior respectivamente.

(38) Fig. 44 y 45. **Tronco de cono**, ABCD, circular, elíptico, etc., recto ú oblicuo; ó **tronco de pirámide** regular ó irregular, recta ú oblicua, de bases paralelas ó no. Por la Regla (36) búsquese el centro de gravedad N de la pirámide total (ó del cono, según el caso) ABT, cuyo tronco forma la parte inferior; y el centro de gravedad S de la pirámide ó cono menor DCT. Búsquese también el volumen de cada uno; así:

El volumen de una pirámide ó cono $= \frac{\text{área de base} \times \text{altura perpendicular}}{3}$

y

$$\begin{matrix}\text{volumen}\\ \text{del tronco}\\ \text{ABCD}\end{matrix} = \begin{matrix}\text{volumen}\\ \text{de la pirámide entera}\\ \text{ó cono ABT}\end{matrix} - \begin{matrix}\text{volumen}\\ \text{de la pequeña}\\ \text{DCT.}\end{matrix}$$

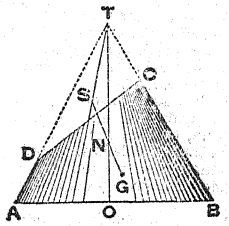

Fig. 44

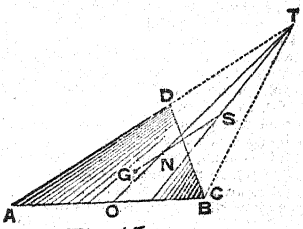

Fig. 45

El centro de gravedad G del tronco ABCD está entonces en la prolongación de la línea SN; y

$$NG = \frac{SN \times \text{volumen de la pequeña pirámide ó cono DCT}}{\text{volumen del tronco ABCD}}$$

(39) **Paraboloide.** G está en el eje y á un tercio de su longitud desde la base.

## LÍNEA DE PRESIÓN
## CENTROS DE FUERZAS Ó DE PRESIÓN

### Posición de la resultante.

**133.** En los §§ 133 á 154 discutiremos la posición de la resultante, ó línea de presión de un sistema de fuerzas paralelas, obrando contra una superficie. Para los cambios en esa posición, dentro de una construcción, debidos á la acción de fuerzas no paralelas, véanse *Arcos*, *Presas*, etc., §§ 251, etc.

**134.** En un sistema de fuerzas paralelas, que obren contra una superficie, la línea de presión es la posición de la resultante de las fuerzas; y el centro de las fuerzas ó centro de presión es el punto en que la línea de presión corta aquella superficie, contra la cual obran las fuerzas.

**135.** Si se toman las longitudes de las líneas que representan las fuerzas, como representando pesos equivalentes, y en una escala dada, la posición de la línea de presión es la que pasa por el centro de gravedad correspondiente á esos pesos. Véase n.° 5, § 131.

**136.** Así pues, en la fig. 55 (*a*), § 117, si las 3 fuerzas *a*, *b*, *c*, se toman como pesos representados en una escala por las flechas *a*, *b* y *c* respectivamente, entonces la resultante R de las 3 fuerzas ocupa la posición de la línea de gravedad de los 3 pesos.

**137.** Digamos más : en una masa de arena, fig. 61*, con una superficie irregular

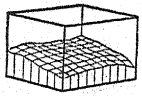

**Fig. 61.**

podemos suponer que la masa está formada por innumerables columnas de arena

* Siguiendo la fig. 60, de las fuerzas paralelas, § 124. Desde la fig. 1 hasta la 45 que tratan del centro de gravedad, están numeradas independientemente del resto de las series de figuras que se refieren á la Estática.

verticales de diferentes alturas y ejerciendo presiones proporcionales á esas alturas. Aquí, también la línea de presión es la línea vertical de gravedad de la masa, y el centro de presión contra la base de la caja es el punto donde dicha línea de presión encuentra á esa base.

**138.** Aunque generalmente consideramos las fuerzas que obran contra superficies, de manera que las líneas que las representan forman un sólido, y no meramente una superficie, sin embargo en la mayoría de los casos que ocurren en ingeniería civil, podemos por conveniencia considerar las fuerzas como concentradas en un solo plano, y por tanto como obrando simplemente contra una línea.

**139.** Así, en el caso de un arco, que ejerce presión contra el arranque, la presión está generalmente distribuída sobre la superficie de apoyo, ó sobre una parte considerable de ella; pero podemos, por conveniencia considerarla como concentrada en un solo plano, situado en el medio y paralelo á las dos caras del arco.

**140.** De manera análoga en el caso de la presión del agua, contra la parte posterior de una presa (ó compuerta, ó contra una pequeña sección de ella, que se extienda desde la superficie del agua hasta el fondo, ó hasta cualquiera profundidad), el agua, por supuesto, ejerce presión sobre la totalidad de la superficie de tal sección; pero podemos, por conveniencia, considerar que la presión está concentrada en un plano vertical normal á la parte posterior de la presa y que la encuentra en el eje vertical de la sección supuesta.

**141.** Acabamos de ver (§§ 138 á 140) que, cuando un sistema de presiones paralelas obra contra una superficie, se puede frecuentemente suponer que obran en un plano contra una sola línea; á saber: la intersección de ese plano con la superficie. También sucede, comúnmente, que tales fuerzas están de tal manera distribuídas á lo largo de esa línea, que las líneas que representan las fuerzas, son ó de longitud igual ó de longitudes que aumentan uniformemente desde un extremo de la línea hasta el otro.

**142.** Así pues, en el caso de que el agua repose sobre una superficie horizontal, fig. 62, la presión está distribuída uniformemente, y el diagrama, fig. (*b*). que

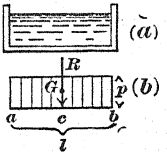

**Fig. 62.**

representa las presiones, es un rectángulo, limitado por una línea horizontal, y su centro de la gravedad G, está en el centro de la figura. De aquí que el centro de presión *c* se halle en el centro de la línea *ab*, en *l*.

Aquí la presión, *p*, es uniforme, y $R = pl$.

**143.** Pero cuando el agua ejerce presión horizontalmente contra una superficie vertical ó inclinada, *ab*, fig. 63, la presión aumenta uniformemente desde *o* en la superficie del agua *b*, hasta un máximo en el fondo *a*; y las presiones horizontales están representadas, en la fig. (*b*), por las ordenadas del triángulo $b'a'd$.

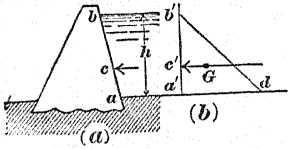

**Fig. 63.**

Puesto que la resultante pasa por el centro de gravedad, G, del triángulo, e centro de presión, *c*, está á tal profundidad, que $ca = {}^{1}/_{3}\,ab$, y $c'a' = {}^{1}/_{3}\,h$. Véase la regla (**14** *c*) del capítulo Centro de Gravedad.

Aquí la presión media horizontal $p$, es la mitad de la presión horizontal máxima en $a$, y la presión horizontal total $= ph$.

**144.** Si de nuevo consideramos sólo las presiones del agua contra cierta *parte*, $ab$, fig. 64, de la superficie posterior de una presa, el diagrama, fig. (*b*), que representa las presiones horiz, se convierte en un trapezoide, compuesto de un paralelogramo

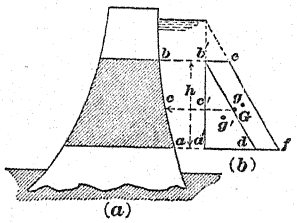

**Fig. 64.**

$b\,f$ y de un triángulo $b\,a'd$, con sus centros de gravedad respectivamente en $g$ y $g'$; y el centro de presión $c$, sobre $ab$, está frente á su centro de gravedad común (centro de gravedad del trapezoide) G. Si $h$ es la profundidad vertical de la porción considerada, entonces

$$a'c' = \frac{h}{3} \times \frac{2b'e + a'f}{b'e + a'f}.$$

Véase Regla 16 de capítulo Centro de Gravedad. Véase también el Centro de presión, en el capítulo de Hidrostática.

## Distribución de la presión.

**145.** A la inversa, si dos superficies, como las de una junta de mampostería, se hallan en un contacto tal que la presión esté regularmente distribuída, ó pueda considerarse así, y si se conoce la posición de la resultante, puede trazarse la figura rectilínea que representa la distribución de la presión, por medio de los principios que acabamos de explicar.

**146.** En las figuras 65 á 68 inclusive, supongamos

$o$ = al centro de la unión $ab$ de las dos superficies;
R = á la presión total = á la resultante de todas las presiones;
$c$ = al punto de aplicación de la resultante R;
$l = ab$ = á la longitud de la unión;
$x = oc$ = á la distancia del centro de presión al centro de la unión;
$y = \frac{l}{2} - x = ac$ = á la distancia del centro de presión al extremo más próximo á la unión;
$p$ = á la presión media $= \frac{\mathrm{R}}{l}$;
$p_a$ = á la presión máxima;
$p'$ = á la presión mínima.

Los §§ 147 á 154 se aplican igualmente si la superficie es horizontal, vertical ó inclinada, y si las fuerzas son normales ó inclinadas respecto á ella.

**147.** Si $x$ no es mayor que $\frac{l}{6}$, ó, en cualquier caso, si la unión puede soportar tensión, tan bien como compresión, tenemos:

$$\text{presión máxima} = p_a = p\left(1 + \frac{6x}{l}\right);$$

$$\text{presión mínima} = p_b = p\left(1 - \frac{6x}{l}\right);$$

Si $x$ excede á $\frac{l}{6}$, y si la unión no puede resistir tensión, véanse §§ 151, 152, 154.

**148. Demostración.** En la fig. 66, en que el paralelogramo $a'd$ representa la presión total R como si estuviera distribuída uniformemente á lo largo de $l$, vemos

que el momento de R, respecto de *o*, que cambia el paralelogramo *a'd* en el trapezoide *a'b'nm*, es equivalente á un par (véase *Pares*, §§ 155, etc.) compuesto de

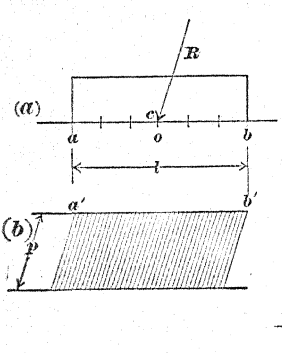

**Fig. 65.**

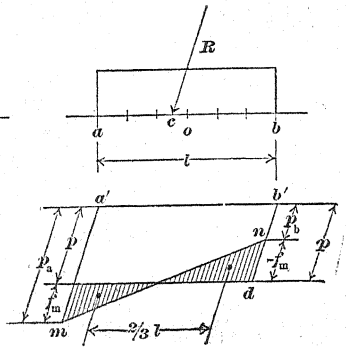

**Fig. 66 (repetida).**

dos fuerzas, á saber: una presión, *f* (no mostrada), distribuída sobre *oa* y representada por el triángulo sombreado á la izquierda, y una tensión, —*f*, ó disminución de presión, distribuída sobre *ob* y representada por el triángulo á la derecha. Las fuerzas, *f* y —*f*, obran por los centros de gravedad de estos dos triángulos, respectivamente; y la distancia de cada uno de estos centros de gravedad al centro, *o*, de la unión, medida paralelamente á la unión, es $= \frac{2}{3} \times \frac{l}{2}$. De aquí que la distancia entre los dos centros de gravedad, medida paralela á la unión, es $= \frac{2l}{3}$. Supongamos que *x* sea la excentricidad, *co*, de R, medida á lo largo de la unión, y supongamos que Aa y Ac (que no figuran) sean las palancas de R y del par, respecto al centro *o*, de la unión. Entonces, puesto que R es paralelo á *f*, y —*f*, Aa á Ac y *x* á *l*, tenemos

$$\text{Aa} : \text{Ac} = x : \frac{2l}{3}.$$

Si R es normal á la unión, entonces: $\text{AR} = x$; y $\text{AC} = \frac{2l}{3}$.

Ahora $$f = \frac{\text{momento de R}}{\text{palanca del par}} = \frac{\text{R} \times \text{Aa}}{\text{Ac}}.$$

Por consiguiente, $$f = \frac{\text{R} \cdot x}{\frac{2l}{3}} = \frac{\text{R}}{l} \times \frac{3x}{2} = p \times \frac{3x}{2}.$$

La presión adicional *media* sobre *oa* (ó tensión media sobre *ob*) es $= \frac{f}{\frac{1}{2}l}$ y la correspondiente presión máxima adicional es

$$f_m = 2\frac{f}{\frac{1}{2}l} = \frac{4}{l} f = \frac{4}{l} p \frac{3x}{2} = p \frac{6x}{l}.$$

Ahora $$p_a = p + f_m = p + p\frac{6x}{l} = p\left(1 + \frac{6x}{l}\right)$$

y $$p_b = p - f_m = p - p\frac{6x}{l} = p\left(1 - \frac{6x}{l}\right).$$

**149.** Si, como sucede en la fig. 65, el centro de presión, *c*, se halla en el centro, *o*, de la superficie, tenemos $x = oc = \text{cero}$, y la presión, R, está uniformemente distribuída sobre la superficie.

**150. « La tercera media ».** Si, como en la fig. 67, $x = \frac{l}{6}$, es decir, si la resultante, R, de todas las fuerzas, corta la superficie en la arista de la tercera media de esa superficie, entonces $p_a = 2\,p$; y $p_b = 0$. Véanse §§ 143 y 148.

**151.** Cuando, como en la fig. 68 (*a*), $x$ excede $\frac{l}{6}$, es decir, cuando el centro de presión, *c*, cae más allá de la tercera media de la superficie de presión, una parte, *sb*, de la superficie, se halla en tensión, siendo la tensión máxima, $p_b$, fig. 68 (*b*), $= p\left(1 - \frac{6x}{l}\right)$ como se ve arriba; la presión máxima $= p\left(1 + \frac{6x}{l}\right)$, y la presión total sobre $as = \frac{p_a \times as}{2} =$ R *más* la tensión en *sb*; pero si, como generalmente sucede en la mampostería, no son capaces las superficies de resistir tensión, la presión total, R, está simplemente concentrada sobre una porción *av*, fig. 68 (*a*), de la superficie siendo $av = 3y$.

Entonces la presión media sobre $av = \frac{R}{av} = \frac{R}{3y}$;

$$p_a = 2\frac{R}{3y} = 2\frac{pl}{3y}.$$

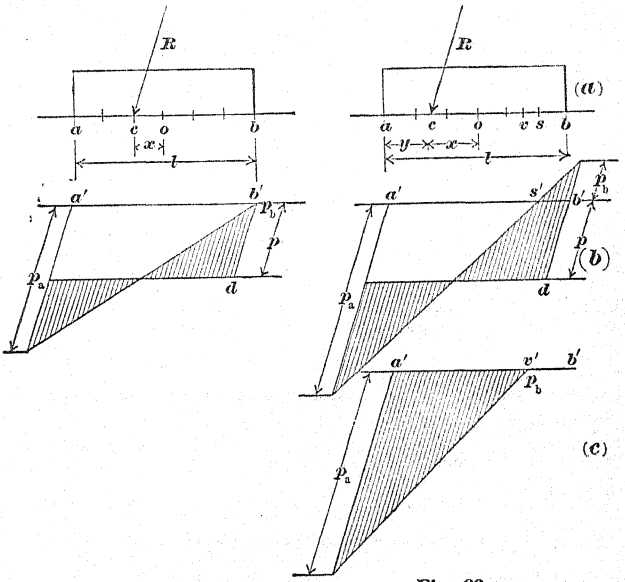

Fig. 67. Fig. 68.

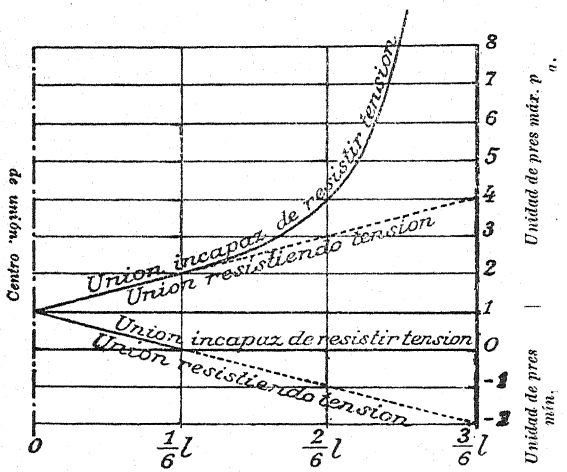
**152.** Por tanto, en una unión que no pueda soportar tensión, fig. 68 (c), $P = 2\frac{R}{3y}$ es el esfuerzo máximo permitido, la distancia *ac*, del centro de presión, al extremo más próximo de la unión, no debe ser menor de $y = \frac{2R}{3p_a}$.

**153.** Si la unión es capaz de resistir tensión, fig. 68 (*b*), sustituímos, en la ecuación, $p_a = p\left(1 + \frac{6x}{l}\right)$, el valor de $x = \frac{l}{2} - y$, y, despejando $y$, tenemos:

$$y = \frac{2}{3}l - \frac{p_a l}{6p}.$$

**154.** Los diagramas de influencias, fig. 69 (véanse §§ 339, etc., y Armaduras §§ 79, etc.), muestran los cambios en las presiones máxima y mínima, $p_a$ y $p$ cuando el centro de presión, *c*, retrocede del centro de la unión *o*. Los diagrama están construídos para una presión media, *p*, de 1. Si las superficies de la unión pue-



*Valores de $x$ = oc = distancia del centro de la unión al centro de presión.*

**Fig. 69.**

den soportar tensión, toda la arista de unión soporta siempre, ó presión ó tensión; y (véanse líneas punteadas fig. 69) la presión máxima, $p_a = p\left(1 + \frac{6x}{l}\right)$, véase § 146, aumenta proporcionalmente con $x$; llegando á ser $= 4p = \frac{4R}{l}$ cuando *c* alcanza el extremo, *a*, de la unión, y cuando $\frac{x}{l} = \frac{1}{2}$. La tensión máxima, *p*, es entonces $= 2\,p = \frac{2R}{l}$. Pero si las superficies no pueden soportar tensión (véanse líneas continuas, fig. 69), el aumento de $p_a$ es proporcional á $x$ sólo mientras $x < \frac{l}{6}$; — es decir, mientras la resultante de todas las presiones cae dentro de la tercera media de la base *ab*. Excedido ese límite, la presión máxima $p_a$, empieza á aumentar más rápidamente que la distancia, *x*, de *c*, al centro *o* de la unión, volviéndose el diagrama una hipérbola rectangular; de manera que, si la resultante pudiera, de hecho, ser aplicada en la arista precisamente de la unión, la presión en aquel punto se volvería infinita.

## PARES

**155. Pares.** Dos fuerzas paralelas iguales, $p$ y $q$, ó $p'$ y $q'$, fig. 70 *, de sentido contrario, se llaman un par. Un par no tiene tendencia á mover el cuerpo†, como un todo en ninguna línea recta. En otras palabras: las dos fuerzas, formando un par, no pueden tener resultante. Su única tendencia es hacer al cuerpo girar sobre su centro de gravedad, G, y en el **plano del par**, es decir, el plano en que están las dos fuerzas. Un cuerpo que tiene un eje fijo puede girar solamente en un plano normal á ese eje.

El verdadero plano de rotación de un cuerpo libre depende de la distribución de la masa en el cuerpo, y no es necesariamente el plano del par.

**156. El momento de un par** es igual al producto de una de las dos fuerzas, $p$ ó $q$, por la distancia, $d$, entre las dos fuezas. Es decir, momento del par $= p.d = q.d$.

**157. Representación gráfica de los pares.** Un par, M ó N, fig. 70, se indica en intensidad, dirección y sentido, por una línea, L ó L' normal al plano del par, colocada de tal manera que, mirando á lo largo de ella hacia aquel plano, el par parece positivo ó que gira de izquierda á derecha, y de tal longitud que represente, en la escala, el momento del par. En la fig. 70, los dos pares M y N son de sentido contrario. De aquí que las líneas L y L', que los representan, estén en direcciones opuestas.

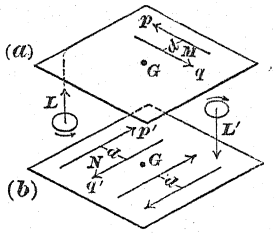


Fig. 70.

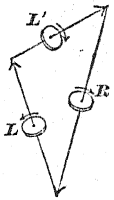

Fig. 71.

**158. Composición de los pares.** Si las líneas L y L', fig. 71, representan dos pares, de acuerdo con el § 157, la línea R, que completa el triángulo, representará de la misma manera su resultante ó antiresultanté. Trazada como está, con su flecha siguiendo las de los otros dos lados, representa su antiresultante. Para indicar su resultante, la flecha de R, y la que indica la dirección de la rotación, deben ser invertidas.

**159. Igualdad de los pares.** Dos pares, M y N, en el mismo plano, fig. 72 ó fig. 73, ó en planos paralelos, fig. 70, son iguales si sus momentos son iguales, sean, ó no, las fuerzas de uno de los pares iguales ó paralelas á las del otro. En la fig. 73, los dos pares, M y N, son de igual sentido; en las figs. 70 y 72, de sentido contrario.

**160.** Puesto que un par no tiene resultante (§ 155), no puede tener antiresultante; es decir, una sola fuerza no puede contrapesar á un par y mantener así

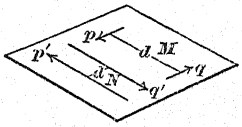

Fig. 72.

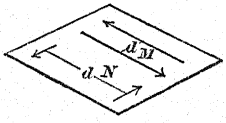

Fig. 73.

el equilibrio. (Pero véase § 168.) Para hacer esto se requiere un par igual y con-

* De las figs. 70 á 75 están dibujadas en perspectiva.
† Véase la nota (*) del párrafo 1.

trario. De este modo, en la fig. 72, se contrapesa el par M por el par igual y contrario N. Si, como en la fig. 72, los dos pares se hallan en un mismo plano, y si encontramos primero la resultante de una de las dos fuerzas no paralelas, como $p$ y $p'$, y luego las de las otras dos, $q$ y $q'$, encontraremos que estas resultantes son iguales y contrarias y que mantienen el equilibrio.

**161. Cualquier par**, como M, fig. 73, **puede ser reemplazado** por cualquier otro par igual, N, en el mismo plano ó en un plano paralelo, y de sentido igual.

**162. Si á una fuerza**, P, fig. 74 ($a$), **agregamos un par**, M, fig. 74 ($b$), en el mismo plano de la fuerza, podríamos reemplazar el par M, con un par igual y equivalente, N, fig. ($c$), compuesto de las fuerzas, — P y P', cada una = P, colocando a — P frente á P, según está indicado. Entonces P y — P se contrapesan, y nos queda sólo P', igual y paralela á P; y, puesto que $Pd=M$, tenemos

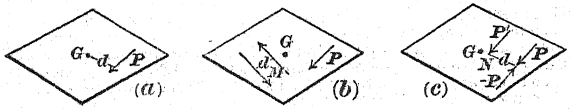

Fig. 74.

$d = \frac{M}{p}$. En otras palabras, el efecto de agregar el par M, fig. ($b$), á la fuerza, P, no es otro sino desviar la acción de P, paralela á sí misma, á una distancia, $d$. Si el par M es izquierdo, como se ve en la figura, P será desviada hacia la derecha (mirando en su propia dirección), y viceversa.

**163.** A la inversa, la fuerza, P, fig. ($c$), es equivalente á la combinación de la fuerza P y del par M, fig. ($b$).

**164.** Por otra parte, teniendo sólo la fuerza P', fig. ($c$), si aplicamos á cierta distancia, $d$, de P', las dos fuerzas opuestas, P y — P, cada una igual y paralela á P', así sustituiremos por P', á la fuerza igual y paralela, P, y un par $=Pd=M$.

**165.** De aquí que también la combinación de la fuerza P y del par M, fig. ($b$), sea equivalente á la combinación de la fuerza P y del par N, fig. ($c$).

**166.** Si el momento del par, M, fig. ($b$), ó N, fig. ($c$), es igual y contrario al momento de la fuerza P respecto al centro de gravedad, G, de un cuerpo, tenemos $d = \frac{M}{P}$ = á la distancia de P á G. En otras palabras, el efecto de tal par es desviar la fuerza P paralelamente á sí misma hasta una línea que pase por el centro de gravedad G.

**167.** Por consiguiente, el efecto de una fuerza, P, fig. ($a$), aplicado á un cuerpo á una distancia, $d$, de su centro de gravedad, G, es equivalente al efecto combinado de una fuerza igual y paralela, P', fig. ($c$), aplicada en el centro de gravedad, y un par (como M, fig. $b$) $=Pd$, y del mismo sentido aplicado á cualquier parte del cuerpo en un plano paralelo á P y P'.

**168.** Se verá que aunque (§ 160) ninguna fuerza por sí sola puede equilibrar á un par, sin embargo, si una fuerza, P, se aplica de tal manera que su momento $Pd$, respecto al centro de gravedad, G, del cuerpo, sea igual y contrario al momento del par, equilibrará la tendencia á rotar, debida al par y la sustituirá con un movimiento de traslación solamente.

**169.** Así, en la fig. 75, donde la fuerza, $p$, obra por el centro de gravedad, G, del cuerpo, supongamos que una fuerza, $-q$, igual y contraria á $q$, sea apli-

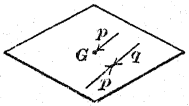

Fig. 75.

cada en la misma línea que aquélla. Se impedirá entonces la rotación y el cuerpo se moverá * bajo la acción de $p$ (=á la resultante de las tres fuerzas), que obra por el centro de gravedad, G, del cuerpo. Se impedirá del mismo modo la rota-

* Véase nota al pie del § 1.

ción si una fuerza *menor* que $q$ es aplicada *más allá* de G, de lo que se encuentra $q$; ó si una fuerza *mayor* que $q$ es aplicada *más cerca* de G, de lo que $q$ se encuentre; siempre que el momento de dicha tercera fuerza respecto á G, sea igual y contrario al del par $pq$. Pero en el primer caso la resultante de las tres fuerzas (que siempre es igual á la tercera fuerza) será menor, y en el segundo caso, mayor que $p$.

**170.** Si á un par se agregara una tercera fuerza, colineal con una de las fuerzas del par, tendríamos el caso de dos fuerzas desiguales y paralelas de sentido contrario. Véase § 112 del capítulo Fuerzas paralelas.

**170*a*. Momentos de los pares.** Las dos fuerzas iguales y paralelas, P, y P', fig. A, en direcciones opuestas, forman un par que gira como las agujas de un reloj = PL = P'L, donde L = á la distancia entre las líneas de acción de las fuerzas. Tomando los momentos de las fuerzas respecto á cualquier punto, digamos A, B, C, ó D, y considerando como *positivos* los momentos de los pares que se mueven como las agujas de un reloj, tenemos :

$$Pm - P'n = P\ (m - n) = P's - Pr = P\ (s - r)$$
$$= Pt + P'u = P\ (t + u) = P \times O + P'L = PL = P'L.$$

En otras palabras, mientras que los momentos, $Pm$, $Pr$, etc., de las *fuerzas son diferentes* para distintos puntos, A, B, etc., el momento $PL = P'L$ *del par* es el *mismo para todos* los puntos.

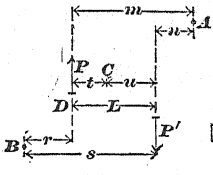

**Fig. A.**

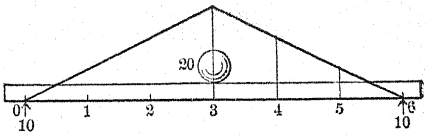

**Fig. B.**

Así pues, supongamos que la viga, fig. B, está dividida por una sección vertica en el número 4. Una fuerza descendente obra sobre la porción de la derecha, en la sección 4 = carga — reacción de la izquierda = 20 — 10 = 10; y en el número 6 obra una fuerza ascendente = reacción de la derecha = 10. Estas fuerzas forman un par de tendencia hacia la izquierda (izquierdo) con momento = 2 × 10 = 20. Obrah sobre la porción de la izquierda, en 0, la reacción de la izquierda = 10; en el número 3, la carga = 20; y, en la sección 4, la reacción de la derecha = 10. Combinando las dos reacciones, encontramos su resultante, = 10 + 10 = 20, en el número 2 (á medio camino entre 0 y 4), formando, con la carga, 20, un par de tendencia hacia la derecha, con momento = 1 × 20 = 20.

En la sección 5, por un procedimiento análogo, encontraremos pares con momentos = 10, y en la sección 3, pares con momentos = 30. Así pues, aunque el momento de un par es el mismo, cualquiera que sea el punto donde sean tomados los momentos, sin embargo, en una viga bajo cierto sistema de fuerzas arreglado de cierta manera, el momento varía de un punto á otro, porque en ese caso los pares son diferentes.

Como se ve, la tendencia rotatoria, en cualquiera sección, es causada por dos pares iguales y contrarios que obran, respectivamente, sobre los dos segmentos; resulta que la tendencia á rotar está contrariada por los pares iguales y opuestos debidos á las fuerzas internas del material, y que obran en la sección, sobre los dos segmentos respectivamente.

## ROZAMIENTO*

**171.** Cuando un cuerpo en bruto descansa sobre otro, las rugosidades y depresiones que forman **las asperezas** de sus superficies en contacto, **se penetran** más ó menos, y para resbalar el uno sobre el otro, tenemos que consumir parte

* « Rozamiento ». Esta palabra para significar el roce ó fricción de una superficie con otra envuelve un error porque implica que debe tener lugar el movimiento necesario al roce ó fricción mientras que encontramo esta resistencia, no solo durante el movimiento de los *cuerpos*, sino tambien antes de que el movimiento tenga lugar. « Resistencias debidas á las asperezas » expresaria mejor el fenómeno.

de la fuerza de rozamiento : ya en *separar* los cuerpos (tal como suspender el de encima) lo suficiente para salvar las asperezas, ya, para destruir algunas, ya para salvar otras.

**172.** La superficie plana mejor pulida como la *xy*, fig. 76, *no* es (como aparece á la vista) un *plano;* es de hecho una superficie dentada, como puede verse con un microscopio suficientemente poderoso, de manera que la fuerza *ab* en lugar de formar el ángulo aparente *abx* con una superficie lisa, *xy*, en realidad se descompone en una serie de fuerzas paralelas, *c*, *d*, *e*, que forman otros ángulos con las superficies, *mm*, *nn*, etc., de aplicación, é inclinadas éstas (á menudo en diversas direcciones) con la superficie general ó media *xy*, como está indicado. Entre estas superficies pueden haber algunas como *mm*, en ángulo recto con la fuerza aplicada, y la fuerza *e* obrará sobre ella en su dirección original, aunque esté aplicada *oblicuamente* á la *aparente* superficie, *xy*. En el caso de dos fuerzas *d* y *e*, aplicadas á las superficies *nn* y *ss*, si la tendencia al resbalamiento es igual en las dos superficies y obran *opuestamente* entre sí, la resistencia *combinada* de las dos superficies *nn*, *ss*, es directamente opuesta á las fuerzas, y equivaldrá á la de una sola superficie en ángulo recto con las fuerzas.

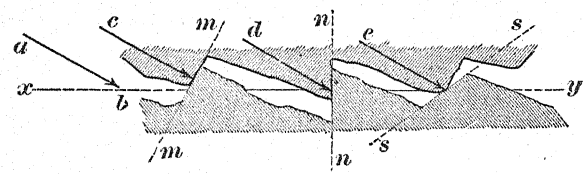

**Fig. 76.**

**173.** Por supuesto que no se trata de investigar la resistencia exacta, en un caso dado, de cada una de esas microscópicas proyecciones. En vez de esto, se encuentra experimentalmente las resistencias *combinadas* que todas las proyecciones presentan al resbalamiento, y á aquella resistencia se llama **rozamiento.**

**174.** El rozamiento siempre tiende á *impedir el movimiento relativo de dos cuerpos entre los cuales obra*, esto es, el movimiento de uno de los cuerpos con relación al otro, no obstante, tiende igualmente á *producir* movimiento * relativo entre cada uno de ellos y *un tercer cuerpo ó cuerpo exterior*. Así, el rozamiento entre una correa y la polea *movida por ella*, tiende á impedir el deslizamiento entre ellas; pero tiende así á hacer que ruede la correa sobre la polea en *movimiento* y pone en movimiento á ésta y á su árbol, *con relación al cojinete* ó *chumacera* en la cual gira el árbol. Este movimiento es contrariado por el rozamiento entre el eje y el *cojinete*, y este frotamiento, á su vez, tiende igualmente á hacer que el *cojinete* gire con el árbol por reacción y hace que la correa se deslice en la polea giratoria.

**175.** El frotamiento entre dos cuerpos que se hallan *en reposo* relativo el uno respecto al otro, se llama **rozamiento estático** ó rozamiento de reposo. El que se ejerce entre dos cuerpos que se encuentran *en movimiento relativo*, se denomina **rozamiento cinemático.**

**176. El rozamiento estático máximo** que se ejerce entre dos cuerpos U y L, fig. 77 (ó la mayor resistencia producida por el rozamiento á una fuerza cualquiera de resbalamiento estando en reposo), es igual á una fuerza (tal como el peso F) que está á punto de hacer que U comience á resbalar sobre L **. De manera que el rozamiento, como las otras fuerzas, puede expresarse por *pesos*, como libras ó kilogramos.

**177.** Una resistencia no puede exceder á la fuerza á la cual se opone ó resiste ***. Por consiguiente, si F es menor que el rozamiento estático máximo existente entre U y L, *la resistencia al rozamiento* realmente ejercida por ellos es también menor.

Cuando F es = al rozamiento máximo (y U está, por tanto, á punto de deslizarse),

---

* Véase nota (*) al pie del § 1.

** Despreciamos aquí el rozamiento de la cuerda y la polea y suponemos que toda la fuerza del peso F se transmite á U por medio de la cuerda.

*** Si una *fuerza* de resistencia excede á la fuerza á que se opone, el exceso ya no es resistencia, sino fuerza motriz.

a resistencia real es=al rozamiento estático. Si F excede a rozamiento estático máximo, el excedente comunica movimiento á U.

**178.** Si á un cuerpo en movimiento se le suprimen ó equilibran en un momento dado todas las fuerzas extrañas ó las resistencias que actúan sobre él, dicho cuerpo se moverá con velocidad uniforme. Por consiguiente, si la fuerza F, fig. 77, es justamente igual al rozamiento cinemático máximo desarrollado entre U y L, la velocidad de ellos será uniforme. Si F excede á aquél, el exceso *acelerará* la velocidad. Si el rozamiento cinemático máximo excede á F, el exceso *retardará* la velocidad. Así pues, la **resistencia real debida al rozamiento** que se ejerce entre dos cuerpos *en movimiento relativo* es=**á su rozamiento cinemático máximo**=á una fuerza (tal como F) que pueda conservarles justamente su velocidad uniforme relativa.

**179.** Por consiguiente, si la superficie horizontal S, sobre la cual descansa L, pudiera hacerse completamente lisa, es decir, sin que produzca rozamiento la presión de L contra el tope *m* (la cual siempre sería entonces igual á la resistencia *real* del rozamiento desarrollada entre U y L), sería también igual á su rozamiento *máximo*, mientras U continúe moviéndose sobre L, y podría ser, por tanto, mayor, menor ó igual á F; pero, cuando U se hallaba en reposo, la presión contra *m* era igual á F y menor (ó á lo sumo=) al rozamiento máximo.

## Coeficiente de rozamiento ó de fricción.

**180.** Desde luego que ninguna superficie puede hacerse *absolutamente lisa*, alguna separación de los dos cuerpos debe en todo caso tener lugar, á fin de evitar las asperezas que existen. Por consiguiente, el rozamiento se produce siempre más ó menos, según la intensidad de la presión perpendicular que tiende á juntar las superficies.

**181.** La *razón* entre el rozamiento máximo, en un caso dado, y la presión perpendicular, se llama **coeficiente de rozamiento** para aquel caso ó

$$\text{Coeficiente de rozamiento} = \frac{\text{rozamiento máximo}}{\text{presión perpendicular}}$$

y rozamiento máximo=presión perpendicular × coeficiente de rozamiento.

Así, si una fuerza F, fig. 77, de 10 kg justamente equilibra el frotamiento máximo desarrollado entre U y L; y si el peso de U (que es la presión perpendicular en este caso, puesto que la superficie entre U y L es *horizontal*) es de 50 kg, el coeficiente de rozamiento entre U y L es entonces $= \frac{10}{50} = .2$.

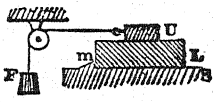

Fig. 77.

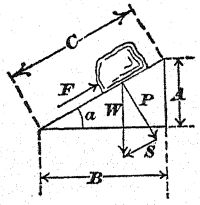

Fig. 78.

**182. El coeficiente se expresa generalmente** en decimales ó por una fracción ordinaria; pero, algunas veces, como en el caso de carros de vías férreas y máquinas, en kg por toneladas (de presión perpendicular), ó por medio del « ángulo de rozamiento ó fricción », en grados y minutos.

**183. Ángulo de rozamiento.** En la fig. 78, sea W=al peso del cuerpo, P, su presión normal sobre el plano, y S=la componente que tiende á hacer resbalar el cuerpo en el plano y hacia abajo. Cuando el ángulo $a$ es tal, que el cuerpo está á punto de resbalar, se llama ángulo de rozamiento ó de fricción. La fricción F y la fuerza S son entonces iguales.

Pero $\frac{S}{P} = \frac{F}{P} = \frac{A}{B}$ = coeficiente de fricción ó rozamiento = tang $a$, y por tanto, $= P \text{ tang } a = W \cos a . \text{ tang } a$.

**184.** Sea R, fig. 79, la resultante de todas las fuerzas que comprimen un cuerpo contra un plano, y N una normal al plano. Si el ángulo $i$ entre R y N excede al ángulo de rozamiento ($a$, fig. 78) entre las dos superficies en contacto, el cuerpo resbalará. Si $i$ no excede á dicho ángulo, la resultante entera R se aplicará al plano y en su propia dirección, y no solamente su componente normal V, como sucedería en el caso en que no hubiera fricción entre las superficies.

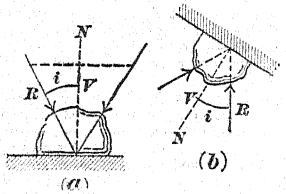

Fig. 79.

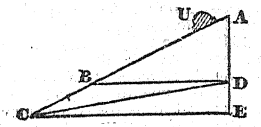

Fig. 80.

**185. Para buscar el coeficiente de rozamiento cinemático,** deslícese uno de los cuerpos U, fig. 80, hacia abajo por un plano inclinado AC, formado del otro cuerpo y que tenga una inclinación conocida ACE mayor que el ángulo de rozamiento (§ 183). Anótese la distancia vertical AE de donde desciende U al deslizarse por AC (AE = AC × sen ACE); también su velocidad real de resbalamiento al llegar á C. Calcúlese la distancia *vertical* AD de la cual tendría que descender *á lo largo del plano* (de A á B) para adquirir aquella velocidad *si no hubiera rozamiento.*

$$\left(\text{AD} = \frac{\text{velocidad}^2}{\text{el doble de la aceleración de la gravedad } g\,^*}\right).$$

Búsquese DE (= AE − AD) y la distancia horizontal EC correspondiente á AC (EC = AC × cos ACE = $\sqrt{\text{AC}^2 - \text{AE}^2}$). Y tenemos entonces :

$$\text{Coeficiente de rozamiento medio al deslizarse de A á C} = \frac{\text{DE}}{\text{EC}},$$

porque si se representa por AE la fuerza *total* de resbalamiento consumida (en mover á U de A á C y vencer el frotamiento), entonces AD representará la parte de AE gastada en *velocidad*, y DE la gastada en *rozamiento*, y como CE representa la presión perpendicular (§ 183),

$$\frac{\text{DE}}{\text{EC}} = \frac{\text{rozamiento}}{\text{presión perpendicular}} = \text{coeficiente.}$$

**186.** O búsquese el seno y la tangente de ACE; y la distancia AC (= tiempo² en segs × ½ $g$ * × sen ACE) que *recorrería* U en un tiempo dado *si no hubiera fricción.* Mídase la dist AB, sobre la que *realmente resbala* en ese tiempo; y encuéntrese BC = AC − AB. Entonces :

$$\left.\begin{matrix}\text{coef del rozamiento medio,}\\ \text{resbalando de A á B}\end{matrix}\right\} = \text{tang DCE} = \text{tang ACE} \times \frac{\text{BC}}{\text{AC}}$$

porque

$$\text{(Primero) AC : AB : BC} = \text{AE : AD : DE}$$

$$\left.\begin{matrix}\text{la velocidad teórica debida á}\\ \text{= la fuerza total de resbalamiento}\end{matrix}\right. : \text{la velocidad real} : \left.\begin{matrix}\text{al retardo por el rozamiento =}\\ \text{a fuerza total de resbal}\end{matrix}\right. : \left.\begin{matrix}\text{la fuerza de resbalamiento em-}\\ \text{pleada en comunicar la velo-}\\ \text{cidad real.}\end{matrix}\right. : \left.\begin{matrix}\text{al rozamiento ó la fuerza de resba-}\\ \text{lamiento requerida para equilibrar}\\ \text{el rozamiento.}\end{matrix}\right.$$

Y si AE es = la fuerza total de resbalamiento, entonces EC es = la presión perpendicular, y

$$\frac{\text{DE}}{\text{EC}} = \text{el coef de rozamiento} = \text{tang DCE.}$$

* $g$ = 32.2 pies = 9 m 81.

(Segundo.) Debido á la semejanza de los dos triángulos ABD; ACE tenemos

$$AC : BC = AE : DE = \frac{AE}{EC} : \frac{DE}{EC} = \text{tang ACE} : \text{tang DCE}.$$

**187.** De 1831 á 1834, el **general Arturo Morin** * hizo experimentos con presiones que no excedían de 30 libs por pulg cuad (2.109 kg por cm cuad) y llegó á las conclusiones siguientes respecto al rozamiento debido al resbalamiento, donde la presión perpendicular es considerablemente menor que la que sería necesaria para gastar apreciablemente las superficies. Éstas fueron generalmente y por largo tiempo consideradas como **tres leyes fundamentales del frotamiento.**

**1.º** El rozamiento máximo entre dos cuerpos es proporcional á la fuerza *total* y normal que los comprime. Por consiguiente :

**2.º** Para cualquier presión *total* perpendicular dada, **el coeficiente es independiente del área de las superficies en contacto.**

Si sobre un apoyo horizontal colocamos un ladrillo que mida (20×10×5) centímetros, y lo colocamos primero sobre su canto (20×5 cm), y luego sobre su cara (20×10 cm), es claro que ahora doblamos el área de contacto, sin que haya variado la presión total (=al peso del ladrillo); pero sí *hemos reducido la presión por cm cuad* á la mitad, puesto que ahora á doble superficie le toca la misma presión. Por consiguiente (permaneciendo el coeficiente de rozamiento prácticamente el mismo), tenemos sólo la mitad del *rozamiento por cm cuad.* Pero tenemos doble número de cm cuad de contacto, y por tanto el mismo rozamiento *total.*

Ahora, si aumentamos ó disminuímos el área de contacto sin variar la presión por cm cuad, la presión total variará por supuesto como el área, y el rozamiento total variará en la misma proporción, porque el coeficiente permanece el mismo. Así, si colocamos dos hojas de papel iguales entre las hojas de un libro (teniendo cuidado de no colocarlas entre las mismas dos hojas) y luego apretamos el libro en una prensa de copiar, necesitaremos como el doble de la fuerza para sacar las dos hojas de la que necesitaríamos para sacar una sola de ellas.

**3.º** Aun cuando el coeficiente del rozamiento *estático* entre dos cuerpos es á menudo mucho mayor que su coeficiente de rozamiento cinemático, sin embargo **el coeficiente de rozamiento cinemático es independiente de la velocidad.**

Esto se aplica también (aproximadamente) al *rozamiento,* y por consiguiente a *trabajo* (en kg por m) que representa el rozamiento vencido en una *distancia* dada, porque entonces el trabajo (=resistencia × distancia) es independiente de la velocidad. Pero cuando se trata de *tiempo dado,* como la distancia varía con la velocidad, es claro que el trabajo también varía como la velocidad.

**188 (a).** Ciertas especies de superficies parece que adhieren mucho mejor sus asperezas cuando están en reposo relativo entre sí, que cuando están en movimiento, aunque éste sea muy lento; y en algunos casos el grado de adherencia parece aumentar con la duración del contacto. De aquí que á menudo hay gran diferencia de intensidad entre el rozamiento en reposo y el rozamiento en movimiento; así el general Morin encontró que en el roble sobre roble, con las fibras en ángulos rectos, la resistencia al resbalamiento estando todavía en reposo y después de haber estado por « algún tiempo en contacto », resultó como un octavo mayor que cuando los pedazos tenían una velocidad relativa de .30 m á 1.50 m por seg.

**(b)** Pero la experiencia demuestra que hasta un choque muy leve es suficiente para eliminar esta diferencia; y como toda construcción hasta las más pesadas están sujetas á choques eventuales (como un puente cercano á un edificio, ó una colina durante el paso de un tren; ó una gran fábrica por el movimiento de sus máquinas, y en numerosos casos por la acción del viento), es conveniente no contar con el rozamiento para la *estabilidad* de las construcciones, más allá de lo que valga su coeficiente en el caso de *movimiento* de los cuerpos entre sí. Cuando deba considerarse como una resistencia, que debemos vencer con fuerzas, debe considerársele bastante *mayor* que la que da la tabla.

---

**189.** Experiencias recientes, con mucho mayores variaciones de presión y velocidad y con aparatos más delicados para apreciar ligeros cambios en el coeficiente, y, aun cuando han dado resultados contradictorios**, demuestran que **las tres leyes en el § 187**, están lejos de ser exactas para superficies que se mueven con grandes velocidades y bajo grandes presiones y que aquéllas **son aproximadamente exactas sólo** para velocidades y presiones ordinarias; pues se ha encontrado que el coeficiente varía con la intensidad de la presión, con la velocidad y también con la temperatura *. Pero en los casos más frecuentes, para el ingeniero,

* Pero después de algunos ensayos las superficies se hacen más suaves hasta reducirse los ángulos de 2° á 5°; los bloques destinados á deslizar tienen peso de 13 kg cada uno, más ó menos.

** Esto no es extraño en vista del grado en que está afectado el coeficiente por la naturaleza de la superficie. Si la forma de las pequeñas asperezas es tal que se penetran entre sí tan bien bajo pequeñas como bajo grandes presiones, y si son demasiado fuertes para que las destruya la presión aplicada, el coeficiente, como se establece en la primera ley, debe ser independiente de la presión. Pero si una presión comprime las asperezas de un cuerpo más estrechamente contra las del otro, el coeficiente debe aumentar bajo semejante presión. Así como si la presión superior destruye las asperezas, mientras que la inferior no puede hacerlo, el coeficiente debe disminuir bajo la presión superior. Las partículas destruídas pueden obrar ó como un lubricante y entonces *reducir* todavía más el rozamiento y su coeficiente; pero si resultan angulosas y duras, lo tienen que *aumentar*. El cambio del área en contacto bajo una presión dada, como produce cambios en el valor de la presión por unidad de superficie, puede producir cambios en el coeficiente, semejantes á los que acabamos de mencionar.

En grandes velocidades las asperezas no tienen tiempo de penetrarse tan bien como en

algunas pequeñas diferencias en la disposición de las superficies, ó en la humedad de aire, causan á menudo mayores variaciones en los coeficientes que las debidas á cualquier cambio probable en la presión, velocidad ó temperatura: de modo que entre los límites del mayor ó menor pulimento podemos generalmente tomar las reglas de Morin como suficientemente exactas.

**190. El profesor A. S. Kimbal,** del Instituto de Ciencias Industriales de Worcester (Massachusets), ha hecho algunos experimentos muy minuciosos respecto del rozamiento entre superficies de madera de pino *. Damos los resultados en la fig. 3, para demostrar simplemente, cómo varía el coeficiente con la velocidad y presión. Nuestra tabla da un coeficiente de .4 para pino sobre pino.

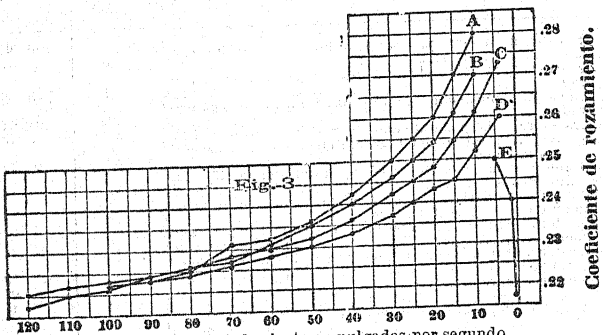

Fig. 3.

La línea A muestra los coeficientes á diferentes velocidades bajo una presión de 1.58 libs por pulg cuad (.11109 kg por cent cuad).

La línea B muestra los coeficientes á diferentes velocidades bajo una presión de 1.59 libs por pulg cuad (.11179 kg por cent cuad).

La línea C muestra los coeficientes á diferentes velocidades bajo una presión de 1.60 libs por pulg cuad (.11249 kg por cent cuad).

La línea D muestra los coeficientes á diferentes velocidades bajo una presión de 1.61 libs por pulg cuad (.11320 kg por cent cuad).

La línea E muestra los coeficientes á diferentes velocidades bajo una presión de 4.17 libs por pulg cuad (.29319 kg por cent cuad).

Se habrá visto que á baja velocidad el coeficiente disminuye cuando se aumenta casi imperceptiblemente la presión por unidad de superficie; pero esta diferencia desapareció á proporción que aumentó la velocidad. A velocidades de .10 á 3 m por segundo el coeficiente disminuye generalmente á proporción que aumenta la velocidad; rápidamente al principio, pero más despacio luego. Esto está de acuerdo con otros experimentos recientes. Pero á muy baja velocidad 2 á 125 mm por seg. El profesor Kimball encontró que el coeficiente (línea E) *aumenta muy rápidamente con la velocidad.*

Hemos hecho grande la escala de coeficientes con el fin de demostrar sus variaciones, la cuales son tan leves que de otro modo serían apenas perceptibles. Experimentos menos precisos no habría sido posible apreciarlos en el diseño.

**191 (a).** En 1878 el **capitán Douglas Galton** y el **Sr. George Westinghouse, hijo,** hicieron cuidadosos experimentos en Inglaterra para determinar

---

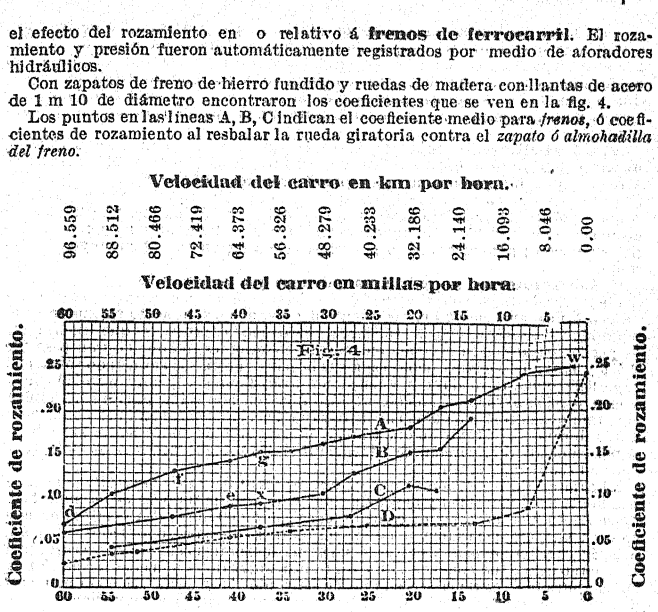
las bajas; por consiguiente debemos esperar un coeficiente menor en aquéllas. Pero las altas velocidades generalmente aumentan el número de asperezas destruídas, y esto puede ó aumentar ó disminuir el coeficiente como se ha explicado arriba. Las grandes velocidades á menudo lo afectan *indirectamente*, aumentando la *temperatura*.

* El Diario de Silliman (Diario Americano de Ciencias), marzo de 1876 y mayo de 1877.

el efecto del rozamiento en o relativo á **frenos de ferrocarril.** El rozamiento y presión fueron automáticamente registrados por medio de aforadores hidráulicos.

Con zapatos de freno de hierro fundido y ruedas de madera con llantas de acero de 1 m 10 de diámetro encontraron los coeficientes que se ven en la fig. 4.

Los puntos en las líneas A, B, C indican el coeficiente medio para *frenos,* ó coeficientes de rozamiento al resbalar la rueda giratoria contra el *zapato ó almohadilla del freno.*



La línea A indica coeficientes obtenidos inmediatamente después de la aplicación del freno.

La línea B indica los coeficientes obtenidos 5 segundos después de la aplicación del freno.

La línea C indica los coeficientes obtenidos 15 segundos después de la aplicación del freno.

La línea D indica los coeficientes de rozamiento contra el riel resbalando una rueda sujeta fuertemente por el freno.

(b) De las líneas A, B y C aparece que el **coeficiente** para el freno que se obtuvo en una cantidad de tiempo dada después de la aplicación del freno, es generalmente mayor en **velocidades pequeñas que en grandes.** Pero cuando la velocidad se mantenía uniforme, **el coeficiente disminuía á proporción que el freno y la rueda permanecían mayor tiempo en contacto.** Así, las líneas A y B muestran que á 37½ millas (60.337 km) por hora, el coeficiente era de .154 cuando el freno fué aplicado primero (punto *g*); pero descendió á .096 en 5 segundos (*x*). La línea A (inmediatamente después de aplicado el freno) muestra un coeficiente mayor (.132 en *f*) á 47½ millas (76.427 km) que la línea B (5 segundos después de la aplicación) muestra á (60.337 km) 37½ millas (.096 en *x*).

La disminución del coeficiente de rozamiento contra el riel con algún tiempo de aplicación del freno fué apenas perceptible.

(c) Cuando el rozamiento del freno (por causa de la disminución de la velocidad y el consiguiente aumento del coeficiente) se hace=á la « adherencia » ó rozamiento estático entre el riel y la llanta de la rueda, la velocidad de rotación decae rápidamente hasta ser menor que la debida á la velocidad del carro; esto es, **la rueda** comienza á patinar ó á *resbalar* á lo largo del riel, y entre .75 y 3 segundos la rotación de la rueda cesa enteramente.

(d) **El coeficiente del riel,** línea D, **es generalmente mucho menor que el coeficiente de los frenos,** líneas A, B y C. La presión sobre el riel

(=peso sobre una rueda) era como de 352 kilog por cm cuad, es decir, excedía en mucho al límite del desgaste. La presión en el freno era como de 14 kilog por cent cuad. Se hicieron algunos experimentos con zapatos de freno que no tenían sino $\frac{1}{3}$ de la superficie usual de contacto, y por tanto el triple de la presión por unidad de superficie bajo la presión dada, y no consiguieron demostrar de una manera concluyente que esto causara ningún cambio notable en el coeficiente.

(e) **El coeficiente del riel**, línea D, así como el coeficiente del freno, **aumenta á proporción que la velocidad disminuye**, y el aumento es lento al principio; pero mucho más rápido á proporción que se hace menor la velocidad; hasta que en el momento de detenerse llega aun á ser mayor que el coeficiente del freno inmediatamente antes de que la rueda patine. Con llantas de acero sobre rieles de hierro á grandes velocidades fué algún tanto mayor que sobre rieles de acero; pero esta diferencia desapareció á medida que disminuyó la velocidad.

(f) **Locomotoras.** La resistencia que tiene que vencer es de $\frac{1}{5}$ á $\frac{1}{3}$ ó más, del peso que descansa sobre las ruedas motrices, es decir, que tienen un coeficiente de .33 ó más aun cuando el coeficiente del acero sobre el acero en movimiento á presión baja es sólo como de .15. Pero los casos son tan diferentes que difícilmente se puede contar con la armonía entre estos coeficientes, porque el gran peso (de 2 á 6 y hasta 7 toneladas sobre cada rueda motriz) está reconcentrado sobre una superficie (donde la rueda toca el riel) tan sólo de 2 pulgs × ½ pulg (6.25 cm cuad), y esta presión excede en mucho, no sólo á las en que están basadas las tablas, sino también al límite de desgaste de la superficie. Además, cualquier punto de la llanta durante el instante en que trabaja, como punto de apoyo por la presión del vapor en el cilindro, permanece estacionario ó fijo sobre el riel, y el rozamiento se hace en ese tiempo estático.

El capitán Galton encontró que **el coeficiente de « adherencia »** era independiente de la velocidad y dependía solamente de la naturaleza de las superficies en contacto. Con un carro de cuatro ruedas con 5,000 libras (2,268 kilog) de peso en cada una, era generalmente de .20 en rieles secos; en algunos casos .25 y aun más. Sobre rieles húmedos ó grasosos, sin arena descendió hasta .15 en un caso; pero el término medio fué como de .18. **Con arena** sobre rieles húmedos fué de .20. La arena aplicada á los rieles secos antes de salir, dió .35 y hasta .40 en el momento de salir y un término medio de .28 próximamente durante el movimiento, y con la arena aplicada á los rieles secos durante el movimiento del carro, éste estuvo á punto de ser arrojado fuera de los rieles por el movimiento producido por las ruedas y el carro.

(g) Debido á la constnacia del coeficiente de « adherencia », bajo condiciones dadas de la llanta y riel, el rozamiento del freno necesario para hacer patinar las ruedas en cualquier caso, ha resultado también prácticamente constante para todas las velocidades. Pero en grandes velocidades, debido al coeficiente inferior del freno, se necesita una presión de freno más alta para producir esta intensidad fija de su rozamiento. El patinamiento también se alcanza en un tiempo mayor que á pequeñas velocidades.

**192.** Si la presión es suficiente para producir desgaste, el rozamiento varía mucho; pero no ha sido descubierta todavía ninguna ley precisa para apreciar las variaciones. Rennie da **la tabla siguiente de coeficientes de rozamiento de superficies secas, bajo presiones gradualmente aumentadas hasta los límites del desgaste.** Se notará que **en esta tabla el coeficiente aumenta generalmente** con la intensidad de la presión.

**Coeficientes de frotamiento de superficies secas, bajo presiones aumentadas gradualmente hasta los límites del desgaste.** (Por G. Rennie, I. C.)

| Presión en kilog por centímetro cuadrado. | Presión en libs por pulgada cuadrada. | Hierro forjado sobre hierro forjado. | Hierro forjado sobre hierro fundido. | Acero sobre hierro fundido. | Latón sobre hierro fundido. |

| 47.25 | 672 | .... | .376 | .403 | .253 |
| 40.85 | 709 | .... | .424 | .... | .234 |
| 55.12 | 784 | .... | .... | .... | .232 |
| 57.72 | 821 | .... | .... | .... | .273 |

**193 (a). Frotamiento rodando** es el que se produce entre la circunferencia de un cuerpo que rueda y la superficie sobre la cual rueda; es algo parecida al de un piñón sobre una cremallera. Al desengranar las asperezas intermedias ó al levantar la rueda sobre un obstáculo *o*, figs. 5 y 6, la fuerza motriz F, en lugar de hacer rodar la una sobre la otra como en la fig. 76, § 172, obra en el extremo de una palanca quebrada FRW, figs. 5 y 6, cuyo otro extremo W obra en dirección perpendicular á la superficie de contacto. En general, cuando se trata de cuerpos rodantes, el brazo de palanta RW, del peso resistente de la rueda y su carga, es siempre mucho menor en proporción al de (FR) que tiene la fuerza F en nuestras exageradas figuras. De aquí que, la fuerza F, requerida para hacer *rodar* una rueda, etc., es de ordinario muchísimo menor que la que se necesitaría para hacerla *resbalar*.

(b) Hay comúnmente **dos maneras de aplicar la fuerza** para vencer el rozamiento rodando : 1.ª (fig. 5) en el eje del cuerpo rodante, como sucede con la fuerza de un caballo aplicada en el eje de una rueda de carro ó la de un hombre en

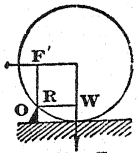

Fig. 5

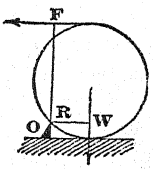

Fig. 6

el eje de una carretilla; 2.ª (fig. 6) en la circunferencia, como cuando los obreros empujan una troza de madera pesada colocada sobre dos ó más rodillos; ó como cuando la armazón de un puente de hierro se desliza hacia atrás y hacia adelante (por contracción y dilatación debida á la temperatura) sobre rodillos ó bolas metálicas. Cuando se aplica la fuerza como en la fig. 5, tenemos además del rozamiento rodante de la circunferencia de la rueda el rozamiento resbalando de su eje en la chumacera. En la fig. 6 tenemos solamente rozamiento rodante, pero en la parte superior é inferior de la rueda.

(c) Cuando los obstáculos *o* son muy pequeños, como en el caso de ruedas de carro sobre caminos planos resistentes ó ruedas de vagón sobre carriles de hierro ó acero, el brazo de palanca (FR) de F viene á ser prácticamente el *radio* en la fig. 5, y en la fig. 6, el *diámetro* de la rueda; mientras que el (RW) de la resistencia es muy pequeño. Por consiguiente, despreciando el rozamiento del eje en la fig. 5, la fuerza F requerida para vencer el rozamiento de rotación en dichos casos es directamente proporcional al peso W de la rueda y su carga, é inversamente al diámetro de la rueda.

Los pocos experimentos que se han hecho respecto al coeficiente de rozamiento por rotación, aparte del rozamiento del eje, son demasiado incompletos para que sirvan de base á reglas prácticas.

(d) **La adherencia** entre la rueda y el riel que pone á una locomotora en capacidad de moverse y mover el tren, ó que tiende á hacer girar una rueda de carro á pesar de la presión del freno, es una resistencia al resbalamiento de la rueda sobre

el carril y no es por tanto rozamiento de rotación, sino de resbalamiento; estático, cuando las ruedas permanecen en reposo ó dan vuelta perfectamente sobre los carriles, y cinemático, cuando « resbalan » ó *patinan*.

**194. El rozamiento de los líquidos** en movimiento en contacto con cuerpos sólidos, **es independiente de la presión**; porque el resbalamiento de las moléculas del fluido por sobre las asperezas de la superficie del cuerpo sólido, está ayudado por la presión de las otras moléculas que las rodean, las cuales tienden á ocupar los lugares de aquellas que han pasado. Por consiguiente, no tenemos para los líquidos coeficiente de rozamiento que corresponda á los de (=*resistencia dividida por presión*) los sólidos. Se cree que la resistencia está en razón directa del área de la superficie de contacto. Recientes investigaciones indican que la resistencia es =un coeficiente × área de superficie × vel $n$, en que $n$ y el coeficiente dependen de la velocidad y de la clase de superficie; y además á pequeñas velocidades, $n=1$; pero á determinada velocidad « crítica » (que varía con las circunstancias) $n$ de repente se hace=2, debido al cambio de la corriente, en determinadas contracorrientes ó remolinos. La resistencia del frotamiento del fluido nace principalmente de las contracorrientes puestas en movimiento.

**195. Tabla de los coeficientes de rozamiento en movimiento de las superficies planas y lisas, cuando se conservan perfectamente lubricadas.** (Morin.)

**El rozamiento ocasionado al botar al agua** la fragata de madera *Princeton* fué calculado por el comité del Instituto Franklin en 1844, con un término medio aproximado de .067 ó un quinzavo ($^1/_{15}$) de la presión durante los primeros .75 de segundo y .022 ó un cuarenta y cincoavo en los 4 segundos siguientes de su movimiento; la inclinación de los durmientes era de 1 en 13, ó 4 grados 24 minutos. Fueron muy bien engrasados con sebo. La presión sobre ellos era = más ó menos 1.12 kg por cm cuad; en los primeros .75 segundo, el buque se deslizó 6.25 cm; en los 4 segundos siguientes, 4 m. 74; total para 4.75 segundos, 4 m 80.

**196. El rozamiento de las superficies lubricadas** varía mucho con la especie de superficie, con el lubricante y con el modo de aplicación. Si el lubricante es de mala calidad y está aplicado escasa y desigualmente bajo gran presión, puede destruirse en ciertos lugares y dejar partes de la superficie seca en contacto. Las condiciones entonces se aproximan á las de superficies no lubricadas. Pero si se usan los mejores lubricantes que se emplean con este objeto, y se aplican regularmente y en cantidad suficiente á fin de conservar las superficies siempre perfectamente separadas, el caso viene á ser prácticamente como un caso de rozamiento de líquidos y la resistencia es muy pequeña. Entre estos dos extremos hay una extensa serie de variaciones (véase la tabla, § 197 *d*), porque el coeficiente varía con el menor cambio en las condiciones. Donde se requiera cierto grado de exactitud, remitimos al lector á los resultados experimentales dados en la muy completa * obra del profesor Thurston, dedicada exclusivamente á este intrincado asunto.

**197 (a).** Los experimentos hechos por el Sr. Arthur M. Wéllington sobre **el rozamiento de los muñones lubricados** †, dieron un aumento gradual y continuo del coeficiente á medida que la velocidad de revolución disminuía desde 5.48 m por segundo (=la velocidad de un carro de 19.308 km por hora) hasta pararse. El aumento fué muy leve para grandes velocidades; pero mucho más rápido para las pequeñas; como en las figs. 3 y 4. En velocidades de .60 m á 5.50 por segundo, el coef fué mucho menor á altas presiones que á bajas; pero al comenzar el movimiento hubo poca diferencia á este respecto. El coef aumentó rápidamente á proporción que se elevó la temperatura de 38° á 66° C.

**(b)** El profesor Thurston, experimentando también con **muñones lubricados** ‡, encontró que al comienzo el coeficiente subió con el aumento de presión, lo que sucedió también con el movimiento cuando la presión excedía en gran manera al máximum (digamos de 34 á 40 kg por cm cuad) admisible en máquinas.

Encontró también que á una gran velocidad el coeficiente *aumentaba* muy despacio (en lugar de continuar disminuyendo) á proporción que aumentaba la velocidad.

**(c)** El profesor Thurston da las siguientes **fórmulas aproximadas para el rozamiento de muñones** á temperaturas, presiones y velocidades ordinarias, y estando el muñón y la chumacera en buenas condiciones y bien lubricados.

(*N. del T.* — Hemos agregado las equivalentes en medidas métricas.)

**Coeficiente para comenzar**: usando medidas inglesas $= (.015 \text{ á } .02) \times \sqrt[3]{\text{presión en libs por pulg cuad.}}$

**Coeficiente** para comenzar: usando medidas métricas $= (.015 \text{ á } .02) \times \sqrt[3]{14.223 \times \text{presión en kg por cm cuad.}}$

**Coeficiente** cuando el eje está **girando**: usando medidas inglesas $= (.02 \text{ á } .03) \times \frac{\sqrt[5]{\text{de velocidad en pies por } \textit{minuto}}}{\sqrt[2]{\text{de presión en libs por pulg cuad.}}}$

**Coeficiente** cuando el eje está **girando** : usando medidas métricas =

$$= (.02 \text{ á } .03) \times \frac{\sqrt[5]{3.2809 \times \text{velocidad en metros por } \textit{minuto}}}{\sqrt[2]{14.223 \times \text{presión en kg por cent cuad.}}}$$

* Friction and Lost Work in Machinery and Mill Work. John Wiley and Sons, New York, 1885.

† Trans Amer Soc of Civil Engrs, New York, Dec. 1884.

‡ Journal of the Franklin Institute, nov. 1878.

A presión como de 14 kilog por cent cuad :

$$\text{Temperatura del rozamiento mínima en grad Fahr} = 15 \times \sqrt[3]{\text{velocidad en pies por } \textit{minuto}.}$$

$$\text{En centígrados y sistema métrico} = (15 \times \sqrt[3]{3.2809 \times \text{velocidad en metros por } \textit{minuto}} - 32)\,\frac{5}{9}.$$

**Advertencia. El brazo de palanca,** con el cual el rozamiento del muñón resiste al movimiento, **aumenta con el diámetro** del muñón.

(d) Las cifras siguientes, elegidas de una tabla de resultados experimentales dados por el profesor Thurston, **demuestran la influencia de la presión, velocidad y temperatura en el coeficiente de rozamiento del muñón;** y de aquí el peligro en que se incurre en semejantes casos al aplicar con toda rigidez las reglas generales. En estos experimentos la naturaleza del muñón y chumacera, el lubricante y su modo de aplicarlo se suponen invariables. En los casos en que éstos varíen pueden ocurrir variaciones en el coeficiente mucho mayores todavía.

**Muñón de acero en chumacera de bronce, lubricado con aceite de ballena.** (*N. del T.* — Hemos agregado las medidas métricas, dejando las inglesas que pueden ser de utilidad.)

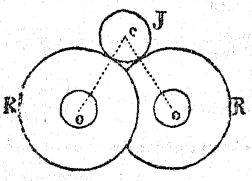
(e) **Cuando se aplica la fuerza primero en un lado del muñón y luego en el lado opuesto,** como en los muñones de manubrio, el rozamiento es menor que cuando la presión resultante está siempre sobre un lado, como en los ejes de los volantes; porque en el primer caso el aceite tiene tiempo para extenderse sobre ambos lados del muñón.

(f) **Rodillos de fricción.** Si un muñón J, en lugar de girar sobre chumaceras ordinarias está soportado por rodillos de fricción R, R, la fuerza que se requiere



para hacer girar á J se reducirá casi en la misma proporción que el diámetro del eje *o*, de los rodillos, sea menor que el diámetro de los rodillos mismos.

Wellington experimentó con una chumacera de rodillo basada en este principio, patentada é inventada por A. Higley. Diámetro de los rodillos R, R, 8 pulgs (.20 m); de sus ejes, *oo*, 1 ¾ pulgs (.044 m); del muñón *c*, 3 ½ pulgs (.088 m). De este modo tenemos teóricamente,

rozamiento del muñón de patente = rozamiento del muñón de 3½ pulgs (.088 m) $\times \frac{\text{diámetro de los ejes } oo}{\text{diámetro de los rodillos R, R}} = \frac{0.044}{0.20}$

ó, como de 1 á 4.6. Bajo una carga de 19.60 kg por cm cuad, el Sr. Wéllington encontró la relación de 1 á 4 al partir del reposo, y de 1 á 2 á la velocidad de un carro de 10 millas (16 km) por hora.

**198 (a). Resistencia del material rodante de ferrocarril.** Se compone del rozamiento rodante entre las llantas de las ruedas y los rieles (las llantas *resbalan* también algunas veces sobre los rieles cuando doblan una curva); del frotamiento de resbalamiento entre los muñones y sus chumaceras, y entre las pestañas ó rebordes de las ruedas y las cabezas de los rieles; de la resistencia del aire; y de las oscilaciones y choques que consumen fuerza motriz por sus movimientos laterales y verticales y que aumentan también los rozamientos de las ruedas y los muñones.

Su intensidad depende en gran parte de la condición de la vía y los rieles (como balasto, alineamiento, superficie, espacio entre las puntas de los rieles, sequedad, etc.); de la condición del material rodante (como el peso que se conduce, calidad de los resortes que se usan, especie y cantidad del lubricante, condiciones y dimensiones de las ruedas, ejes, etc.); de las pendientes y curvas; de la dirección y fuerza del viento, y de muchas consideraciones menores. Los experimentos dan resultados muy opuestos.

**(b)** Durante el verano de 1878, el **Sr. Wéllington** hizo experimentos con carros de plataforma y carros cubiertos, cargados y vacíos; carros de pasajeros y carros dormitorios á velocidades variables desde 0 hasta 56 km por hora. Los carros salieron rodando (por su propio peso) por una pendiente uniforme, de .7 por ciento, y de una extensión de 1,950 m. Sus resistencias fueron calculadas como en el § 185. « Los rieles eran de hierro, del peso de 30 kilog por met, y la vía estaba bien provista de balasto, bien recta y presentaba muy buena superficie; pero no era estrictamente de primera clase. » Los números aproximados siguientes se dedujeron de los experimentos hechos por el Sr. Wéllington sobre carros provistos de muñones ordinarios *. (*N. del T.* — Hemos agregado los datos en sistema métrico.)

**Resistencia en libras, y también en kilog por tonelada de (2,240 libs), 1,016 kilog, de peso del tren,** en vía recta y á nivel, en buenas condiciones.

| Velocidad del tren en kilómetros por hora. | Velocidad del tren en millas por hora. | Carros vacíos. | | | | | | | | Carros cargados. | | | | | | | |

**(c)** Con el muñón de rodillo de patente Higley, la resistencia al partir no fué sino como de 2 kg por tonelada.

**(d)** Como á la mitad del camino en que se hizo el experimento, había una **curva** de un ángulo de desviación de 1° (1,746.47 m de radio) de 914 m de largo, con su riel exterior elevado de 7½ á 10 cm como 152 m antes de llegar á la curva. En los primeros 152 m de curva, la resistencia fué mayor que la que se encontró inmediatamente antes de llegar á ella de .27 kilog á .95 kilog (término medio .50 kilog) por tonelada. En los últimos 152 m este exceso había disminuído de .09 kilog á .41 kilog (término medio .25 kilog) por tonelada. Debido á la continuidad de la pendiente de descenso en la curva, la velocidad aumentó á proporción que el tren la recorría; pero no se vió claramente si la disminución en

* Transactions, American Society of Civil Engineers, Feb. 1879.

la resistencia de la curva fué debida al aumento en velocidad ó al hecho de que las oscilaciones producidas por la entrada á ella cesaron gradualmente á proporción que el tren avanzó.

(c) **El Sr. P. H. Dudley,** haciendo experimentos con su « **dinamógrafo** » * obtuvo resultados de los que se han deducido los siguientes :

**Resistencia de un tren en libs y en kilog por tonelada (de 2,240 libs = =1,016 kilog) de peso del tren (incluyendo pendientes).** (*N. del T.* — Hemos agregado los datos en sistema métrico.)

| Descripción del tren. | | | Viaje. | Término medio de velocidad por hora. | | Término medio de resistencia. | |
|---|---|---|---|---|---|---|---|
| Carros cargados. | Carros vacíos. | Peso en toneladas 2,240 libs =1,016 k. | | Millas | Km. | libras | Kilog. |
| 20 | 2 | 526 | Toledo á Cleveland : 95 millas (152.8 km) | 20 | 32.18 | 8.34 | 3.77 |
| 37 | 0 | 633 | Cleveland á Erie : 95.5 millas (153.6 km) | 20 | 32.18 | 7.67 | 3.47 |
| 25 | 2 | 458 | Erie á Búffalo : 88 millas (141.6 km) | 20 | 32.18 | 8.89 | 4.02 |

Con los trenes largos y pesados del ferrocarril L. S. y M. S. Ry, de 600 á 650 toneladas, se requería menos combustible con la misma máquina para correr trenes de 30 á 32 km que para los de 16 á 19 km, debido al hecho de que en las grandes velocidades se usó mucho más el vapor por expansión; por consiguiente se logró mayor economía.

**199. El trabajo que se necesita para vencer el rozamiento** á cualquiera distancia, es = al rozamiento en kilogs × la distancia en metros. Un cuerpo que haya salido resbalando ó rodando por un plano horizontal, y que luego se le abandone á sí mismo, rodará ó resbalará una distancia dada, efectuando el trabajo que acabamos de apreciar, y su energía cinemática será entonces (= su peso en kilogs × su velocidad$^2$ en mets por segundo ÷ $2g$ †). Este valor debe ser igual al primero. Por tanto, **la distancia en metros** recorrida por el cuerpo deslizándose ó rodando sobre un plano horizontal, es : (*N. del T.* — Usando sólo el sistema métrico.)

$$= \frac{\text{su energía cinemática medida en kilográmetros al salir}}{\text{rozamiento en kilogs}}$$

$$= \frac{\text{peso del cuerpo en kilogs} \times \text{velocidad inicial}^2 \text{ en mets por segundo}}{\text{peso del cuerpo en kilogs} \times \text{coeficiente de rozamiento} \times 2g \dagger}$$

$$= \frac{\text{velocidad inicial}^2 \text{ en metros por segundo}}{\text{coeficiente de rozamiento} \times 2g \dagger}$$

**El tiempo requerido,** en segundos, es :

$$= \frac{\text{distancia en mets encontrada}}{\text{velocidad media en mets por segundo}} = \frac{\text{distancia en mets}}{\frac{1}{2} \text{ veloc. inicial en mets por segundo}}$$

Supongamos dos locomotoras semejantes, A y B, tirando cada una de un tren sobre una vía á nivel y recta; A á 10 km y B á 20 km por hora. La resistencia total de cada máquina y tren (que por conveniencia suponemos ser independiente de la velocidad) es de 1,000 kilogs. De aquí que la fuerza ó presión total del vapor en los dos cilindros que se requiere para equilibrar el rozamiento y mantener de este modo la velocidad, es la misma en cada máquina. Al hacer *diez km* esta fuerza efectúa la misma cantidad de trabajo (1,000 kilogs × 10 km = 10 millones de kilográmetros) en cada máquina y con el mismo gasto de vapor en cada una; aun cuando B debe suministrar vapor á sus cilindros *dos veces más ligero* que A, á fin

* Un instrumento para medir el esfuerzo de la barra de tracción de una locomotora, la fuerza que ésta ejerce sobre el tren.

† $g$ = aceleración de la gravedad = 9.81 m.

de *mantener* en ellos la misma presión. En *una hora*, la fuerza en A hace 10 millones de kilográmetros como antes; pero la fuerza en B hace (1,000 kilogs × 20 km =) 20 millones de kilográmetros, con doble gasto de vapor que A.

Pero, en verdad, la resistencia de un tren dado es mucho mayor á grandes velocidades. Véase la tabla § 198 (*b*). Y si suponemos aún que la resistencia es igual en ambas velocidades, B debe ejercer más fuerza para *adquirir* una velocidad de 20 km por hora, que A para adquirir una de 10.

**200. Talud natural.** Cuando se depositan lentamente las substancias granuladas, como : arena, tierra, granos, etc., como cuando son paleadas, en una cortada ó de un carro, el ángulo formado por la superficie inclinada del montón del material con un plano horizontal, se llama talud natural. Este ángulo depende de la fricción y adherencia entre las partículas del material y varía, á menudo, transcurrido algún tiempo, en el mismo material, con las condiciones atmosféricas, etc., y especialmente con la humedad.

**201.** Cualquier fuerza, *p*, fig. 85, obrando sobre un cuerpo, B, basta para mover el cuerpo (véase nota *, § 1) con tal de que exceda á la suma, S, de todas las

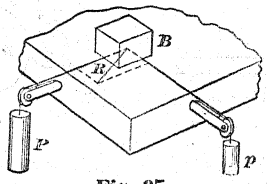

**Fig. 85.**

resistencias, incluyendo la fricción entre B y la superficie sobre que reposa B, ó si produce, con cualquiera otra fuerza ó fuerzas, P, una resultante, R, mayor que S.

Si antes de ser aplicada *p*, el cuerpo está en movimiento uniforme, P = S; cualquier fuerza, *p*, por pequeña que sea, es suficiente para cambiar la dirección del movimiento. Esto explica la facilidad con que un eje de revolución puede resbalar longitudinalmente en sus chumaceras y, el hecho de que es más fácil sacar un corcho de una botella si se le comunica antes un movimiento de torsión en el cuello de la botella.

## PALANCAS

**202. Géneros de palancas,** figs. 86. Las palancas se clasifican de acuerdo

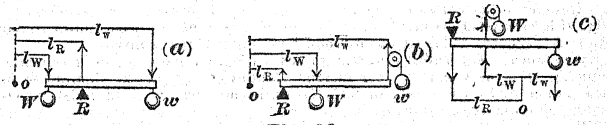

**Fig. 86.**

con la posición relativa de su « potencia », « resistencia » y « punto de apoyo »; así * :

Fig. (*a*), 1.er género. Punto R entre potencia *w* y resist W;
— (*b*), 2.º — Resist W entre potencia *w* y punto R;
— (*c*), 3.er — Poten W entre resist *w* y punto R.

En el 2.º género, el brazo de palanca de la potencia es necesariamente mayor que el de la resistencia. En el 3.º, viceversa.

**203.** En la fig. 86, tomando los momentos de las fuerzas, respecto á un punto cualquiera como *o*, se tiene, para el equilibrio :

Fig. (*a*), $W \cdot l_W - Rl_R + w \cdot l_W = 0$;
— (*b*), $W \cdot l_W - Rl_R - w \cdot l_W = 0$;
— (*c*), $W \cdot l_W - Rl_R + w \cdot l_W = 0$.

* Cuando las palancas se usan para levantar pesos, ó para vencer otras resistencias, la fuerza aplicada se llama « potencia » y la fuerza ó fuerzas que se van á vencer, « resistencia ».

**204. Palancas combinadas**, fig. 87. Se usan cuando no hay espacio para un solo brazo de palanca suficientemente largo. En un sistema de palancas,

$$\frac{\text{resist}}{\text{poten}} = \frac{\text{producto brazos palanca de potens}}{\text{prod brazos palanca de resists}} = \frac{8\times10\times2}{2\times\ 1\times4} = 20.$$

Las tres palancas de la fig. 87, tomadas separadamente, y empezando por la potencia extrema, da :

$$\frac{\text{resist}}{\text{poten}} = \frac{8}{2} = 4; \quad \frac{10}{1} = 10; \quad \frac{2}{4} = \frac{1}{2}; \quad \text{y } 4\times10\times\frac{1}{2} = 20.$$

como antes.

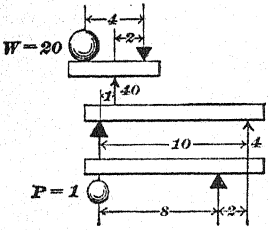

Fig. 87.

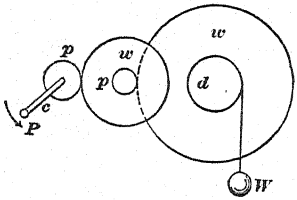

Fig. 88.

**205. Engranajes dentados. Ruedas y piñones**, fig. 88. Éstos son una serie de palancas compuestas. La potencia se aplica generalmente donde va el manubrio en *c* y la resistencia al cilindro *d*. La rueda más ancha se llama « la rueda »; la menor, *p*, el piñón. Sea *c*=radio del manubrio, *d*=el del cilindro, *m*=al producto de los radios de los piñones, *n*=al producto de los radios de las ruedas. Entonces, despreciando la fricción :

$$\frac{\text{resist}}{\text{poten}} = \frac{c\ .\ n}{m\ .\ d}.$$

En lugar de los diversos radios, se puede, por supuesto, usar los diámetros ó las circunferencias correspondientes, y como los dientes tienen necesariamente entre sí igual « paso » (longitud medida sobre la circunf), se acostumbra tomar el número de dientes de las ruedas ó piñones en lugar de los radios.

Las palancas combinadas y los engranajes se emplean para convertir velocidades pequeñas en altas y para vencer fuerzas grandes con pequeñas. Cuando se usan para aumentar la velocidad, la posición de la potencia y de la resistencia son contrarias á las que se indican en las figs. 87 y 88.

**206.** Siempre que la poten y resist se equilibren, ya sea en una palanca simple, ó en un sistema de palancas, si suponemos que ambos se mueven alrededor del punto de apoyo, sus respectivas velocidades estarán en la misma porporción que sus brazos de palanca; es decir, que si la palanca de la potencia es 2, 5 ó 50 veces mayor que la de la resist, la poten se moverá 2, 5 ó 50 veces más ligero que la resist. Por tanto, observando estas velocidades, se determina la proporción de sus brazos de palanca. La resist y la poten están entre sí en razón inversa de sus velocidades y también en razón inversa de sus brazos de palanca.

**207.** No se obtiene ninguna ventaja mecánica con sólo aumentar la *longitud* de una palanca, como por ejemplo, encorvándola, como en *abo*, fig. 4, § 13, ó dándole una inclinación hacia la línea de acción de la potencia, P, como en *om*, *ou*, *on*.

**208.** Así, en la fig. 89, que representa una palanca encorvada, *afb*, la longitud de la *palanca* ó de cualquiera de sus miembros como *fb*, no debe confundirse con el brazo de palanca de la fuerza. Éstos pueden, ó no, ser iguales. Por ejemplo, la parte *fb* es mucho más larga que *fa;* sin embargo, si los brazos de palanca *fa* y *fc*, de las fuerzas ó pesos, son iguales, los pesos *m* y *n* deben también ser iguales para que haya equilibrio.

**209.** Si se quita el peso $m$, una fuerza, $c$, ó $s$, ó $y$, ó $d$, con palanca $= c'$, $s'$, $y'$, $d'$, respectivamente, puede ser aplicada en cualquier punto, como $b$, para equilibrar el momento de $n$. En todo caso, esta fuerza debe ser tal que

$$\text{fuerza} \times \text{su brazo de palanca} = n \,.\, af.$$

Por tanto,

$$\text{fuerza} = \frac{n \,.\, af}{\text{brazo de palanca de la fuerza}}.$$

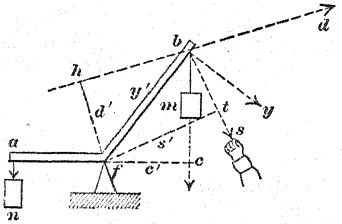

**Fig. 89.**

**210.** Por consiguiente, también la fuerza requerida es *menor*, como cuando en $y$, es *perpendicular* á la longitud de $fb$, pues la palanca (que evidentemente no puede exceder á $fb$) es entonces la *máxima*. La fuerza requerida aumenta cuando se desvía en una ú otra dirección de la línea $by$ (perpendicular á $fb$) y se aproxima más á $fb$; pues su brazo de palanca disminuye constantemente. Ninguna fuerza, por más grande que fuera, podría compensar el momento de $n$ respecto de $f$, si fuera aplicada en la dirección $fb$ ó $bf$, pues tal fuerza no tendría momento respecto á $f$.

**211.** De modo análogo, en la fig. 90, el momento respecto al punto $a$, de una carga W, colocada en $b$, es $=$ W . $ac$, y lo mismo sería colocada en $c$.

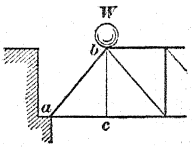

**Fig. 90.**

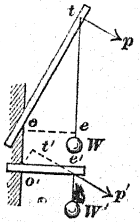

**Fig. 91.**

**212.** En la fig. 91, también los momentos W . $oe$ y W . $o'e'$, de los pesos iguales W y W', son iguales. Pero si las fuerzas $p$ y $p'$ son aplicadas en direcciones perpendiculares á la viga más larga, $ot$, la palanca $ot$ de $p$ llega á ser como 6 veces la de ($o't'$) de $p'$. Por tanto, una fuerza $p$ aplicada en $t$, tiene más ó menos el mismo momento inclinado que una fuerza paralela $= 6\,p$, aplicada en $e'$.

## ESTABILIDAD

**213.** Figs. 92. Si la resultante R (fig. *a*) de la fuerza P y del peso W se sale de la base, como está indicado, entonces el momento P de su tendencia á volcarlo, fig. 92 (*b*), respecto al pie *n*, excederá al momento de estabilidad del peso W en el mismo punto, y el cuerpo se volcará alrededor de *n*. Si no, quedará en pie.

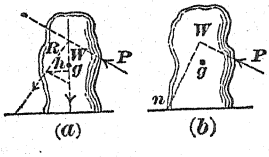

Fig. 92.

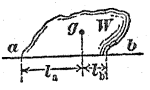

Fig. 93.

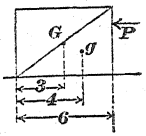

Fig. 94.

**214.** Suponiendo estabilidad suficiente para evitar el volcamiento, el cuerpo se deslizará si la componente horizontal *h* de R, fig. 92 (*a*), excede á la resistencia del frotamiento y á las demás que existan.

**215.** En la práctica, el borde *n*, ó el piso debajo de éste, pudieran ceder, si la piedra girará sobre aquél ó si R cayese cerca de *n* (véanse §§ 145, etc.); pero esto pertenece a la resistencia de los materiales. Poniendo concreto, etc., entre la base y el peso, se añadiría una tercera fuerza y cambiaría el problema.

**216.** Debido al mayor brazo de palanca, $l_a$ fig. 93, de W, respecto al punto *a*, el momento de estabilidad es mucho mayor respecto á éste que respecto al punto *b*.

**217.** En la fig. 94, sea G=2 kg; *g*=1 kg; los brazos de palanca=3, 4 y 6 m, como está indicado. Así, el momento de estabilidad del cuerpo rectangular G opuesto á una fuerza horizontal P, es=3 G=3×2=6 kilográmetros, y el momento del triángulo bajo, *g*, es=4*g*=4×1=4 kgm; así, aunque el cuerpo grande pesa el doble del triángulo bajo, sólo tiene 1.5 veces su estabilidad.

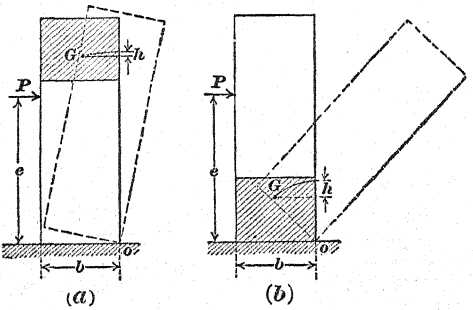

Fig. 95.

**218. Volcamiento.** Supongamos que, en la fig. 95 (*a*) y (*b*), la parte sombreada sea de plomo y el resto de madera, y, además, que el centro de gravedad de todo el cuerpo esté en cada caso en G. Entonces, como el peso W es el mismo en ambos casos, como también la palanca de su estabilidad respecto al punto $O = \frac{b}{2}$, el momento de estabilidad $= \frac{1}{2} b.W$, es el mismo en ambos casos, como lo es también la fuerza P, requerida para equilibrar dicho momento, cuando se aplica á una altura dada *e*. En los que se refiere al volcamiento, el peso, W, queda constante; el brazo de palanca, el momento de estabilidad, y el requerido de volcamiento, decrecen, llegando á ser=0 cuando el cuerpo alcanza la

posición que indican las líneas de puntos. Si la elevación, $e$, queda constante, la fuerza, P, necesaria para volcarlo, decrece en la misma proporción que el brazo de palanca.

**219.** Pero, cuando tratamos del volcamiento por la sola fuerza de la gravedad, deben llevarse los cuerpos á la posición indicada por las líneas de punto. Esto equivale á levantar el peso del cuerpo á una altura = á la distancia $h$, á que sube el centro de gravedad G. Así

$$\text{trabajo de volcamiento} = W.\ h.$$

Como $h$ es mayor en la fig. ($b$), este trabajo es mayor en este caso. En ingeniería civil se considera generalmente el valor de la fuerza para *comenzar* el volcamiento, con preferencia á la requerida para *completarlo*.

**220.** Es claro que la estabilidad contra el volcamiento está afectada y puede ser aumentada por otras fuerzas que no son el peso solo. Así, la estabilidad de una pila de puente se aumenta de ordinario con el peso del puente si éste se le aplica simétricamente. De otro modo el peso del puente aumentará ó disminuirá la estabilidad de la pila según las circunstancias.

**221.** El coeficiente de estabilidad es, en cualquier caso, la relación entre los momentos de estabilidad y de volcamiento; es decir:

$$\text{Coeficiente de estabilidad} = \frac{\text{momento de estabilidad}}{\text{momento de volcamiento}}.$$

**222.** Sea, en la fig. 96, el peso W de la piedra = 10 kg; G, su centro de gravedad, y $og = 2$ m. Entonces, el momento de estabilidad, respecto á $o$, es $10 \times 2 = 20$ kgm, si $on$ es = 5 m, una fuerza $P = \frac{20}{5} = 4$ kg, tendrá precisamente en equilibrio el momento del peso W, y excepto en el borde $o$, sobre la base $om$ no se ejercerá ninguna presión, aunque la piedra esté en contacto con la base. Si la fuerza P excede de 4 kg, la piedra empezará á girar alrededor de $o$, y si es menor, ejercerá una presión sobre la base $om$.

Supongamos que la piedra está sostenida en $o$ y en $m$ solamente. El brazo de palanca de la fuerza sustentadora R, en $m$, es $= om = l$. Sea P = 1 y la base $om$ = 4.5 m. Entonces, para el equilibrio, se tendrá:

$$W.\ og - P.\ on - R.\ om = 0;$$

ó bien $$20 \text{ kgm} - 1 \times 5 = 4.5 \times R;$$

de donde $$R = \frac{20 - 5}{4.5} = 3.33\ldots \text{ kg}.$$

En otras palabras: una fuerza vertical hacia arriba, R, de 3.33 kg en $m$, mantendrá el equilibrio.

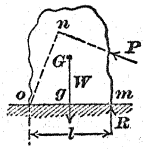

**Fig. 96.**

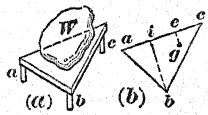

**Fig. 97.**

**223.** Sea, en la fig. 97 ($b$), $g$ el centro de gravedad, del peso W y de la mesa combinados, fig. 97 ($a$). Entonces, la reacción hacia arriba de $b = \frac{W.eg}{ib}$. Las de $a$ y $c$ se encuentran del mismo modo.

**224.** En la fig. 98, sea $h$ la fuerza horizontal ejercida por la parte izquierda del semiarco, sobre la clave del otro semiarco de la fig., y sea $e$ su brazo de palanca respecto al punto $o$. Sea W el peso del semiarco y de la enjuta obrando como un

solo cuerpo rígido, y $l$ su brazo de palanca respecto al punto $o$. Entonces, para e equilibrio, se tendrá:

$$h \cdot e = W \cdot l; \qquad h = \frac{W \cdot l}{e}.$$

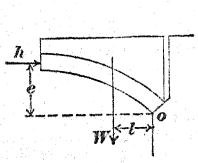

Fig. 98.

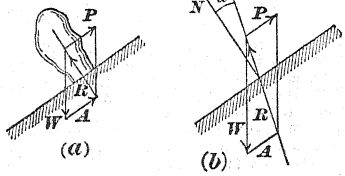

Fig. 99.

## Estabilidad en los planos inclinados.

**225.** Estabilidad en los planos inclinados, fig. 99. Aquí, como en el § 213, si la resultante R, de la fuerza P y el peso W, se sale de la base, es decir, si el momento de l volcamiento excede al de estabilidad, el cuerpo se volcará; si no, se sostendrá.

La fuerza, P, requerida para evitar el volcamiento, es=á la antiresultante A del peso W y de la reacción R; y la reacción R=á la antiresultante de P y W.

**226.** Despreciando la fricción, como en la fig. 99 ($a$), R será normal al plano. Tomando en cuenta la fricción, fig. 99 ($b$), R formará con la normal, N, al plano un ángulo, $a$, que no excederá el ángulo de fricción entre el cuerpo y el plano. R puede estar hacia arriba ó hacia abajo respecto á N.

**227.** En la fig. 100, el cuerpo B opone menos estabilidad al volcamiento, alrededor de $a$, que su semejante A, cuando la fuerza $n$ lo empuja hacia abajo; pero opone mayor estabilidad al volcamiento alrededor de su arista $c$ bajo la acción de una fuerza que lo empuje hacia arriba.

**228.** El cuerpo C, que se volcaría sobre una base horizontal, tendrá estabilidad contra el volcamiento, situándolo en un plano inclinado, como en D. Suponiendo $ao = tc$, cualquier fuerza vertical hacia arriba tendrá el mismo momento, para el

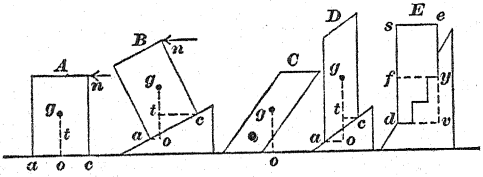

Fig. 100.

volcamiento, apliquésela en $a$ ó en $c$. Pero cualquier fuerza horizontal, aplicada á cualquier altura, como en $g$, tiene mayor palanca, $go$, empujando hacia abajo, que cuando empuja hacia arriba. En este caso su palanca es sólo $gt$.

**229.** Las construcciones fabricadas sobre pendientes tienen tendencia á resbalar. Esto se evita dividiendo la pendiente en escalones horizontales como en $dy$, fig. E; pero las caras verticales de los escalones dividen la trabazón de la mampostería, y, además, en el lado más alto, $sd$, las juntas son más numerosas y hay más argamasa que en la cara corta de arriba, $ey$, quedando así la tendencia á una desigual estabilidad y la parte baja más alta tiende á separarse de la de arriba, como sucedería en una fundación que tuviera un piso firme en una parte y compresible en otra. Así, cuando las circunstancias lo permitan, es preferible poner horizontal toda la base como en $dv$; ó si la construcción tiene que soportar presiones hacia abajo, $v$ puede estar más bajo que $d$ y las hiladas de mamposterías, colocadas con la correspondiente inclinación.

## LA CUERDA

**230. La cuerda**, figs. 101 (*a*) y (*b*), y 102 (*a*) y (*b*). En los §§ 230 á 239 consideramos las cuerdas como completamente flexibles, inextensibles, sin fricción ni peso é infinitamente delgadas.

**231.** Sea P la fuerza exterior aplicada en el nudo, ó gancho *o*, y sea R la resultante de los esfuerzos $s_1$ y $s_2$, ó bien *oa* y *ob*, en los dos segmentos *om* y *on* de la cuerda. Entonces, para el equilibrio, R debe ser igual y colineal con P.

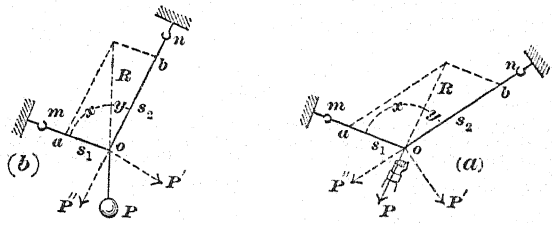

**Fig. 101.**

**232.** Conociendo el valor de P (=R), las tensiones $s_1$ y $s_2$ se encontrarán por el § 36; y viceversa dadas $s_1$ y $s_2$ se encontrará R (=P) por el § 35. O véase el §.40.

**233.** Si, como en las figs 101 (*a*) y (*b*), la fuerza P se aplica á la cuerda, en *o*, por medio de un nudo fijo incapaz de resbalar á lo largo de ella, de manera que los segmentos *om* y *on* sean de longitud fija, y el ángulo, $x+y$, entre ellos, también lo sea, entonces la fuerza puede ser aplicada en cualquier dirección como P, ó P', pasando entre los dos segmentos de la cuerda; y las componentes $s_1$ y $s_2$ serán iguales solamente cuando R forme ángulos iguales, $x$ é $y$, con los dos pedazos de la cuerda. Si la dirección de la fuerza, como P'', coincide con uno de los segmentos, como *on*, éste transmitirá toda la fuerza, P'', y el otro nada.

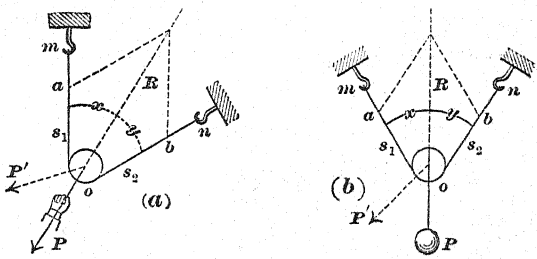

**Fig. 102.**

**234.** Pero si, como en las figs 102 y 103, la fuerza P se aplica á la cuerda, por medio de un anillo, polea ó gancho, etc., resbaladizo, entonces para el equilibrio las dos tensiones $s_1$ y $s_2$ deben ser iguales y también los dos ángulos $x$, $y$; y si suponemos que la dirección de la fuerza P cambia á la posición P', el gancho ó polea y la cuerda se ajustarán de nuevo, como lo indica la línea de puntos, fig. 103, hasta que el gancho ó polea llegue al equilibrio en el punto *o'* en que los ángulos $x'$, $y'$, sean iguales y también las tensiones $s_1'$ y $s_2'$.

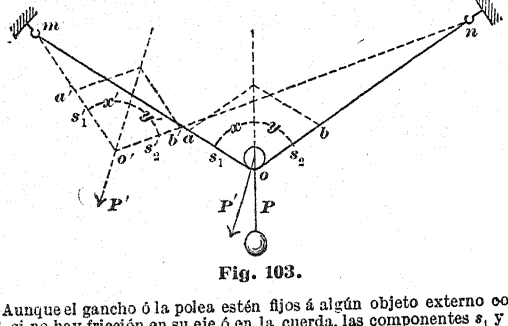

**Fig. 103.**

**235.** Aunque el gancho ó la polea estén fijos á algún objeto externo como en *o*, fig. 104, si no hay fricción en su eje ó en la cuerda, las componentes $s_1$ y $s_2$, serán iguales y su resultante R dividirá en dos partes iguales el ángulo $x+y$, entre ellas.

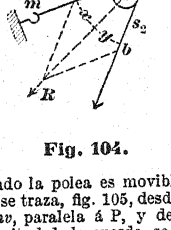

**Fig. 104.**

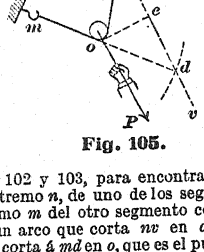

**Fig. 105.**

**236.** Cuando la polea es movible, figs. 102 y 103, para encontrar la posición que tomará, se traza, fig. 105, desde un extremo *n*, de uno de los segmentos *on* de la cuerda, *nv*, paralela á P, y del extremo *m* del otro segmento con el radio = *mo* + *on* = longitud de la cuerda, se traza un arco que corta *nv* en *d*. Tómese el medio *e* de *nd*; trácese *oe* normal á *nd*, que corta á *md* en *o*, que es el punto deseado.

**237.** Ya sea *o* un nudo fijo ó polea movible, estará siempre situado en la periferia de una elipse, cuyos focos son los extremos, *m*, *n*, de la cuerda.

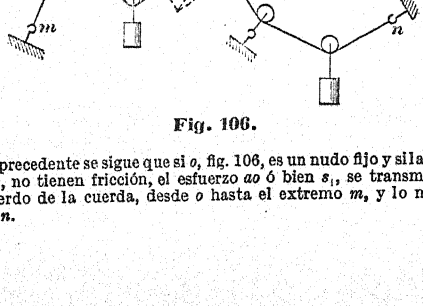

**Fig. 106.**

**238.** De lo precedente se sigue que si *o*, fig. 106, es un nudo fijo y si las otras poleas, ganchos, etc., no tienen fricción, el esfuerzo *ao* ó bien $s_1$, se transmitirá por todo el lado izquierdo de la cuerda, desde *o* hasta el extremo *m*, y lo mismo la *bo* = $s_2$, de *o* hacia *n*.

**239.** Advertencia. Obsérvese que, en la fig. 107 (*b*), la tensión en todas las cuerdas es doble de la tensión en las cuerdas correspondientes de la fig. 107 (*a*), aunque en cada fig. está suspendido de la polea un peso=4. Así, si el peso fuera el de un hombre colgado de la cuerda, y si la cuerda en la fig. (*a*) tuviese *exactamente* la fuerza necesaria para sostenerlo, ésta se reventaría, si él le da un extremo de la cuerda á otro para que la sostenga ó si amarra el extremo, como en la fig. (*b*).

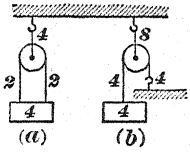

**Fig. 107.**

## La máquina funicular.

**240.** Cuando los ángulos $x$ é $y$, figs 101, etc., son muy grandes, una fuerza muy pequeña, P, equilibra una gran tensión, $s_1$ ó $s_2$, en la cuerda. Cuando $x=y=90°$, tenemos cos $x$=cos y=0, y $s_1=s_2$=infinito, por muy pequeña que sea P. Si la línea *mn*, que une los extremos de la cuerda, es horizontal ó inclinada, el peso de la cuerda solo obra como una fuerza P. Por tanto ; « No hay fuerza, por grande que sea, que pueda estirar una cuerda horizontal hasta ponerla en línea recta. »

**241.** En la máquina funicular se aprovecha la ventaja de que, cuando el ángulo total $x+y$, entre los dos segmentos de la cuerda, se aproxima á 180°, una pequeña fuerza P equilibrará grandes tensiones $s_1$ y $s_2$. Así, supongamos, en la fig. 108, que W representa un bote muy pesado (todo visto de plan) que debe ser acercado á tierra. Un extremo de la cuerda se ata á la proa, la cuerda se pasa, por un poste liso *n*, á otro *m*, alrededor del cual se le dan una ó más vueltas; y un hombre, de pie en *e*, sostiene la cuerda con alguna flojedad, mientras otros, con una fuerza P, tiran de la cuerda entre *m* y *n*, trayéndola á la posición *mon*. Si los ángulos $x$ é $y$ son iguales, la componente en el segmento *on* excede á P, tanto como el ángulo $x$ excede á 60°, y una tracción igual á esta componente (deducida, por supuesto, la rigidez de la cuerda y la fricción con el poste) acercará el bote un poco hacia tierra. Entonces, cobrando cuerda en *e*, se vuelve á poner el cable recto en *mn* y se repite la operación cuantas veces sea necesario.

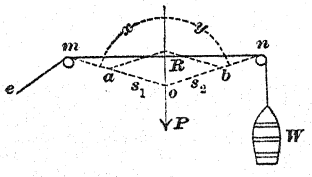

**Fig. 108.**

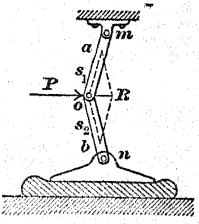

**Fig. 109.**

## La junta de codillo.

**242.** Esta es, simplemente, la inversa de la máquina funicular, con un nudo fijo y la fuerza P y las componentes $s_1$ y $s_2$ obrando por compresión y no por tensión. Como la unión no puede moverse á lo largo de los brazos, la fuerza P se puede aplicar en la dirección que se quiera; pero se acostumbra aplicarla de modo que forme aproximadamente ángulos iguales con los dos brazos.

## La polea.

**243.** Las figs. 110 muestran las relaciones de las tensiones y pesos en diferentes disposiciones de poleas fijas y movibles. Así, en (*a*), 1 kg equilibra 1 kg, en (*b*) $2_p$ en (*c*) y en (*d*) 4 kg. En cada caso, si los cuerpos se ponen en movimiento, sus velocidades estarán en razón inversa de sus masas. Véase § 206.

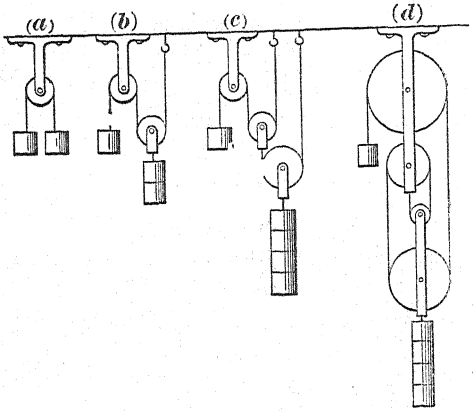

**Fig. 110.**

**244.** La polea simple, fig. 110 (*a*), se usa simplemente para cambiar la dirección de la fuerza, porque éstas en los dos extremos de la cuerda son iguales; pero en la polea compuesta, figs. 110 (*b*), (*c*), (*d*), una fuerza pequeña (la potencia), moviéndose rápidamente, en una parte de la cuerda, equilibra fuerzas mayores (la resistencia), moviéndose en la otra parte. Así, la polea compuesta se usa para vencer lentamente grandes resistencias, por medio de pequeñas fuerzas que se mueven con rapidez.

**245.** Para poner tal sistema en movimiento * (para levantar el peso) se necesita romper el equilibrio, haciendo que la « potencia » exceda á la tensión en la cuerda, debida al peso. Pero, ya engendrado el movimiento, continuará indefinidamente si la potencia es suficientemente mayor que el peso para vencer las resistencias de la fricción, etc.

## La cuerda ó cadena cargada.

**246.** En las figs 111, el principio del polígono de las cuerdas, §§ 86, etc., se aplica al caso de una cuerda ó cadena flexible, que sostiene cuatro pesos, $p_1 \ldots p_4$, en puntos fijos, ejerciendo una tensión horizontal†, H, en su extremo bajo, y una inclinada, R, en su extremo alto. Los pesos $p_1 \ldots p_4$, se representan por la línea vertical 0-4, fig. 111 (*a*); la tensión horizontal, H, por 0-*c*; la intensidad y dirección de la tensión inclinada, R, en la parte alta de la cuerda, por 4-*c*, y la tensión en los segmentos, 1-2, 2-3 y 3-4, por los radios, 1-*c*, 2-*c*, y 3-*c*, respectivamente.

**247.** La tensión horizontal, H (=á la componente horizontal de la tensión en cada segmento), es uniforme á lo largo de la cuerda; pero, la componente vertical de la tensión en cualquier segmento, es igual á la suma de los pesos entre ese segmento y la polea, *m*. Así, la componente vertical (0-2, fig. *a*) de la tensión *c*-2, en el segmento 2-3, es $=p_1+p_2$; en el segmento 3-4, es $0\text{-}3=p_1+p_2+p_3$, etc.

**248.** Si todos los pesos, incluyendo W, se aumentan en la misma proporción, como se indica por las líneas de puntos en la fig. 111 (*a*), ó se disminuyen en la misma proporción, los nuevos triángulos, *c'*, 4', 0, etc., fig. (*a*), serán semejantes al

---

* Véase la nota (*) al pie del § 1.
† Véase la nota (*) al pie del § 249.

viejo, y el perfil de la cuerda, fig. (*b*), quedará inalterable, aunque las tensiones en los segmentos es claro que aumentarán ó disminuirán en la misma proporción.

**249.** En la fig. 111 se ha hecho el peso, W, que es necesariamente igual á la tensión horizontal H * (véase la Cuerda, §§ 230, etc.), igual también á la suma de los

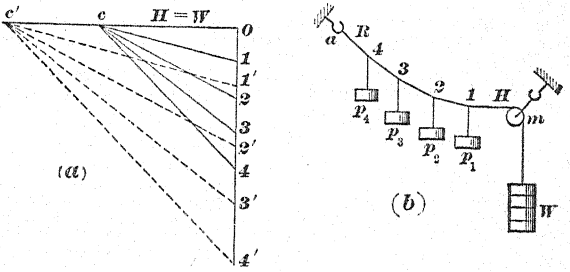

Fig. 111.

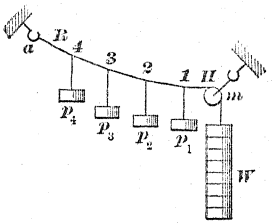

Fig. 112.

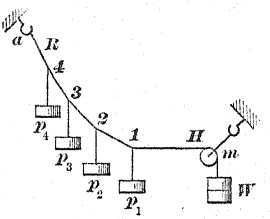

Fig. 113.

pesos, $p_1 \ldots p_4$. Cuando es así, el segmento de cuerda, *a*–4, próximo al soporte, *a*, y la línea correspondiente, *c*–4, fig. (*a*), formarán 45° con la vertical.

**250.** Pero si, quedando los pesos $p_1 \ldots p_4$ invariables, se levanta la polea *m*, de manera que H sea horizontal *, se obtendrá una curva suave, achatada, como en la fig. 112; y, para el equilibrio, H (=W) debe hacerse *mayor* que la suma de $p_1 \ldots p_4$. Por otra parte, si se coloca la polea, *m*, más baja que en la fig. 111 (siendo H siempre horizontal), se obtiene una curva más ahondada, como en la fig. 113; y H (=W) debe hacerse *menor* que la suma de $p_1 \ldots p_4$.

* En las figs. 111, 112 y 113 se supone el peso, W, y la posición de la polea, *m*, de tal manera dispuestos respecto al soporte *a*, que la tensión, H, quede horizontal.

## ARCOS, PRESAS, ETC., LÍNEAS DE EMPUJE Y DE RESISTENCIA

### El arco.

En los §§ 251 á 257 se dan los elementos de la teoría comúnmente aceptada del arco. Para las consideraciones prácticas, véanse los §§ 258 á 266 y Puentes de piedra.

**251** Si las figs. 111, 112 y 113 se invierten, los segmentos de cuerda representarán puntales que resisten la compresión, como lo hacen las piedras de un arco de mampostería, fig. 114.

### Línea de empuje. Línea de resistencia.

**252.** En el caso de un arco, fig. 114, suponiendo * que el empuje horizontal, H, en la clave, *m*, y la reacción, R, del arranque, *a*, obra en el centro (ó en algún otro punto definido) de la clave y del arranque, respectivamente, sus intensidades y la dirección de la reacción, R, pueden encontrarse por medio del Triángulo de las fuerzas, § 51, ó por los Momentos, § 224. (Véase § 257.) Suponemos entonces que el semiarco y su enjuta están divididos por planos verticales *, fig. 114 (*b*),

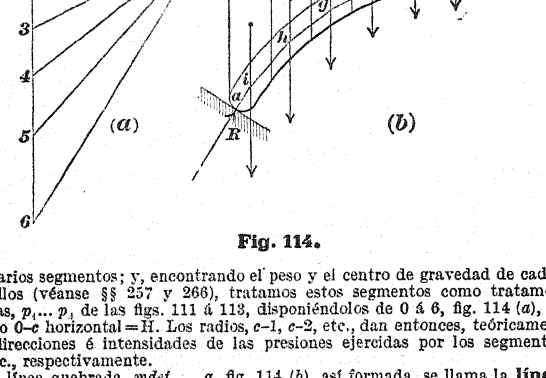

**Fig. 114.**

en varios segmentos; y, encontrando el peso y el centro de gravedad de cada uno de ellos (véanse §§ 257 y 266), tratamos estos segmentos como tratamos las cargas, $p_1 \ldots p_1$ de las figs. 111 á 113, disponiéndolos de 0 á 6, fig. 114 (*a*), y trazando 0–*c* horizontal = H. Los radios, *c*–1, *c*–2, etc., dan entonces, teóricamente *, las direcciones é intensidades de las presiones ejercidas por los segmentos, 1, 2, etc., respectivamente.

La línea quebrada, *mdef*. . . . *a*, fig. 114 (*b*), así formada, se llama la **línea de empuje**, ó línea de las resultantes. Ella corresponde á los polígonos de cuerda de las figs. 111 (*b*), etc. *

**253. La línea de resistencia** es una línea quebrada que une los puntos en donde las varias resultantes, que forman la línea de empuje, cortan las respectivas juntas entre las piedras del arco.

**254.** Cuando los planos, por los cuales se supone dividido el arco en segmentos, son verticales *, como en la fig. 114 (*b*) y como sucede en la mayor parte de los arcos reales, las líneas de empuje y de resistencia, fig. 115, coinciden prácticamente; pero, si estos planos están lejos de ser verticales, como en la fig. 115, las dos líneas se separan, siendo siempre la línea de resistencia la exterior.

Así, en la fig. 115 (donde la línea de empuje es la continua, y la línea de resistencia la puntuada), notando dónde la resultante *a* corta la junta A, dónde la resultante *b* corta la junta B, etc., se verá que las dos líneas prácticamente coinciden hasta la junta C, donde empiezan á divergir.

---

* Véase Consideraciones prácticas, §§ 258, etc.

**255.** En el § 252 supusimos que el arco y su enjuta están divididos en segmentos verticales que, en este caso, ejercen presiones verticales. La línea de resistencia teórica, así obtenida, puede pasar, en algunos lugares y especialmente en arcos rebajados, del espesor del arco; de modo que, si no obrasen otras fuerzas,

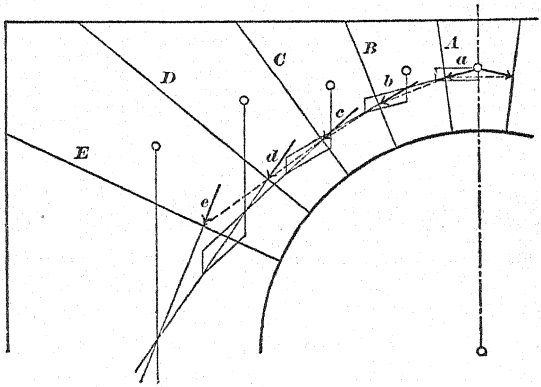

**Fig. 115.**

el arco se abriría en tales lugares; en el intradós, cuando la línea de resistencia corta el trasdós, y viceversa; pero tal ruptura se impide ordinariamente con otras fuerzas, tales como las presiones horizontales ó inclinadas de la enjuta. La verdadera línea de resistencia se reduce así al interior del espesor del arco. En general, la verdadera línea de resistencia, fig. 116, se acerca al trasdós en la clave y al intradós en los riñones, de modo que el arco tiende á hundirse en la clave (abriéndose allí en el intradós) y á levantarse en los riñones (abriéndose en éstos en el trasdós), como lo indica la figura.

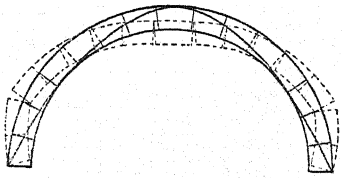

**Fig. 116.**

**256.** A fin de evitar cualquier tendencia de las juntas á abrirse en uno ú otro lado, debe trazarse de tal modo el arco que la línea de verdadera resistencia esté en todas partes dentro del tercio medio (véanse los §§ 145, etc.) del espesor del arco.

**257.** En general, el trazado de un arco se obtiene por una serie de aproximaciones. Así, debe suponerse de antemano una forma de arco y de enjuta, á fin de encontrar su centro común de gravedad y poder determinar el empuje horizontal, H, y la reacción del arranque R, como en el § 252; y si después es necesario modificar la forma adoptada al principio, á fin de satisfacer las exigencias del § 256, ó por otras razones, tendremos que recomputar H y R, modificando otra vez el diseño, y así se continúa.

## Consideraciones prácticas.

**258.** Si bien las líneas de empuje y resistencia, basadas en las suposiciones precedentes, se hallan fácilmente, existe mucha incertidumbre en cuanto á las posiciones de dichas líneas en un arco de mampostería.

**259.** En primer lugar, no sabemos por qué puntos en la clave y en el arranque, respectivamente, pasan las resultantes H y R.

**260.** Además, hemos supuesto que los pesos en el arco, como en la cuerda, figs. 111 á 113, son incapaces de obrar de otro modo que verticalmente; mientras que los muros de arranque y los rellenos que forman una gran parte del peso en un arco de mampostería pueden ofrecer resistencias que obren en otras direcciones. Si la carga fuera un líquido, como por ej. agua, sus presiones sobre el arco serían radiales, como las de las partículas de vapor, en una caldera, sobre los tubos de la caldera, y esta condición está probablemente y aproximadamente satisfecha en el caso de una carga de arena limpia, seca; y, menos exactamente, en el caso de un relleno de tierra. Por tanto, aunque la determinación de las líneas teóricas de empuje y de resistencia en un arco se facilita por la suposición de que el arco está exactamente representado por la cuerda invertida, la diferencia entre los dos casos debe tenerse presente cuando se deduzcan conclusiones prácticas de las líneas así encontradas.

**261.** En muchos casos, las líneas teóricas de empuje y de resistencia cortan los intradós ó los trasdós en algunos lugares saliéndose del arco; de modo que éste caería inevitablemente (véase § 255), si no fuera por las resistencias horizontales ó inclinadas ejercidas por las partes superiores de los pies derechos y por los muros y rellenos.

**262.** Por tanto, á fin de determinar la línea de resistencia real, no sólo debemos saber por qué puntos, en la clave y en el arranque, respectivamente, pasan las resultantes H y R, sino que también habremos de averiguar y tomar en cuenta las posibles resistencias horizontales é inclinadas de los muros y relleno. Pero, como esto es de ordinario impracticable, nos contentamos, ó con determinar las líneas teóricas de empuje y de resistencia, como se dispone arriba, y entonces apreciamos, tan bien como se pueda, las resistencias de los arranques; ó bien razonando por analogía con lo que sucede en las construcciones reales. Véase Puentes de piedra.

**263.** Si la cuerda invertida representara exactamente la verdadera línea de empuje en un arco de mampostería, las claves, en arcos elípticos ó muy rebajados, habría que hacerlas anchas fuera de toda regla, á fin de que la línea de resistencia no dejara de pasar en ninguna parte por el tercio medio de su espesor (véanse §§ 145, etc.); y quizás sería entonces racional hacer corresponder aproximadamente el perfil del arco con la línea de empuje, que habitualmente se acerca á una parábola. Pero, debido á las resistencias del arranque, la línea real de empuje, aun en arcos semicirculares, raras veces excede en mucho al tercio medio.

**264.** Cuando hay un muro ó un profundo relleno continuo, sobre un arco, el muro ó el relleno formarán sobre él un arco natural, como lo indican las líneas

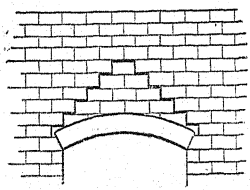

**Fig. 117.**

quebradas en la fig. 117; y sólo esa porción debajo de ese arco caería si se suprime el arco. Por tanto, sólo á esta porción se la considera con propiedad, ejerciendo presión sobre el arco.

**265.** Despreciando la fuerza de la mezcla, la inclinación de cada junta entre dos piedras de arco debe naturalmente ser tal, que el ángulo, entre el empuje, en cualquier junta y una normal á esa junta, sea menor que el ángulo de frotamiento. Véanse §§ 183, 184.

**266.** Acontece á menudo que los arranques ó el relleno son de menor densidad que el arco. En tales casos, á fin de facilitar el modo de encontrar los centros de gravedad de los segmentos, podemos, antes de dividir el semiarco y sus arranques en segmentos verticales (§ 252), darle á la parte más liviana del relleno una altura menor, tal que suponiéndola de igual densidad que el arco, pese lo mismo que pesaba el relleno. Las áreas de los varios segmentos (como se ven en el dibujo) así reducidos, pueden entonces tomarse como representando sus pesos. Así, en

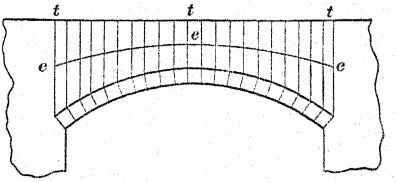

**Fig. 118.**

la fig. 118, *ttt* representa el término del relleno, y la línea curva *eee* representa el término de un relleno de peso igual al anterior por metro corrido y de la misma densidad que el arco. Cuando, como en la fig 119, la carga consiste en una serie de arcos, podemos suponer que el arco principal soporta una serie de pesos concentrados en los pilares de los arcos de arriba.

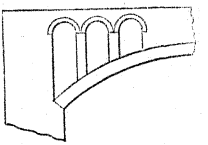

**Fig. 119.**

## La presa de mampostería.

**267.** Una presa debe ser incapaz de resbalar, en su base ó en cualquier plano dentro del cuerpo de la presa, incapaz de volcarse ni de demolerse por el peso del material. No debe tampoco agrietarse en ninguna de sus caras.

**268.** La presa estará segura contra resbalamientos si la resultante de todas la presiones, sobre cualquier superficie, forma, con una normal á esa superficie, un ángulo menor que el ángulo de rozamiento de esa superficie. Véanse §§ 183, etc. En la práctica, la base de la presa se baja bien hasta el cimiento de roca, como se indica en la fig. 122 (*a*), y se evita la continuidad de las juntas, colocando las piedras de modo que alternen las juntas. El ángulo de fricción llega á ser así, en efecto, de 90° y el resbalamiento no puede ocurrir sin cortar las piedras mismas.

**269.** Si el material es suficientemente fuerte para resistir á la trituración, bajo las fuerzas que obran sobre él, y si la resultante de todas las fuerzas que obran sobre cualquier sección cae dentro del cuerpo de la presa, ésta no se volcará. Pero véase § 270.

**270.** Para una presión total dada sobre cualquier sección, la máxima presión por unidad de superficie en la sección será menor cuando la resultante pase por el punto medio de la sección. Véase Centro de presión, §§ 133, etc. Generalmente es imposible conseguir esto, pero la presa debe trazarse de tal suerte, que, bajo la máxima presión, el material no resista más de lo que indique su coeficiente de seguridad para trituración. Si esto se hace y si para todo caso se mantiene el centro de presión dentro de la tercera media (§ 150) de cada sección horizontal en toda la presa, no habrá tendencia á que se raje ninguna de las caras de la presa.

**271.** Sea la fig. 120 un bloque de piedra (que descansa en un cimiento sólido) destinado á sostener de un lado la presión, *p*, del agua tranquila. Por el centro de

gravedad, $g$, del bloque, trácese $o'N$ verticalmente, y representando el peso W del bloque. Entonces, el punto, $s$, donde $o'N$ encuentra el cimiento, es el centro de presión del bloque sólo, esto es : sin el agua.

**272.** Sea $h$ la profundidad del agua detrás del bloque y supongamos el bloque de un m de largo, medido normalmente al papel. Entonces la cantidad, en kg, de la presión del agua, contra la cara posterior vertical, $ab$, es $p = 1{,}000h \times \frac{1}{2} h$ (un m cúb de agua pesa 1,000 kg) y su centro de presión está á una profundidad, $d = \frac{2}{3} h$ debajo de la superficie del agua,

**273.** Componiendo $p$ con W (§ 35), obtenemos R como resultante de ellas, y $r$ como centro de presión sobre el cimiento cuando el bloque está sosteniendo la presión del agua.

**274.** Supongamos que la fig. 121 represente varios bloques semejantes superpuestos. Sea

$g_1$ = centro de grav; $p_1$ = centro de pres de agua, para bloque 1;
$g_2$ = — — $p_2$ = — — — bloques 1 y 2 combinados;
$g_3$ = — — $p_3$ = — — — 1, 2 y 3 comb., etc.,

Entonces, hallando $r_1$ y $s_1$; $r_2$ y $s_2$; $r_3$ y $s_3$, etc., para las juntas 1–2, 2–3, 3–4, etc., como antes, tenemos los puntos $r_1$, $r_2$, $r_3$, etc., en la línea de resistencia para la presa llena y los puntos $s_1$, $s_2$, $s_3$, etc., en la línea de resistencia para la presa vacía.

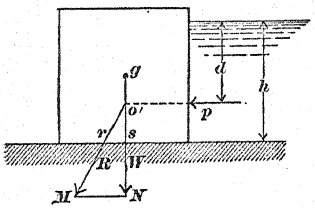

Fig. 120.

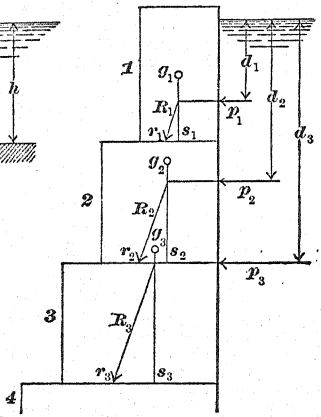

Fig. 121.

**275.** En la fig. 122 ($a$) las curvas $uu$ y $dd$, indican los límites, aguas arriba y aguas abajo, respectivamente, de la tercera media del plano que separa cada dos bloques, suponiendo el perfil vertical atrás; y los puntos $r_1 \ldots r_7$ y $s_1 \ldots s_7$ son puntos en las correspondientes líneas de resistencia para la presa llena y la presa vacía respectivamente.

**276.** Si bien la teoría requeriría que la sección transversal de la presa terminara en ángulo agudo arriba, siempre se hace con cierto espesor, como se indica en la fig. 122 ($a$).

**277.** Para la junta 2-3 podemos suponer que el bloque 2 se había trazado, al principio, rectangular, como en la línea de puntos $ca$, fig. 122 ($c$) (que muestra los bloques 1 y 2 en mayor escala); pero esto hace que, el centro de presión, $r'$, para la presa llena, caiga fuera de la tercera media de la base estrecha, $ab$. Nosotros estudiamos por tanto la forma trapezoidal $cib$, con su base más ancha $ib$, y encontramos que, con ésta, el centro de presión, $r_2$, aunque más lejos de la cara interior que antes, cae dentro de la tercera media de dicha base más ancha. El resto del perfil se determina por ensayos semejantes.

**278. Método gráfico.** Supóngase que la sección transversal se divida, por sec-

ciones horizontales, en numerosos bloques, 1, 2, 3, 4, etc., de una profundidad aproximada=al ancho superior de la presa. En la fig. 122 (*b*) trácese 0–1, 1–2, 2–3, 3–4, etc., verticalmente, para representar, en escala, los pesos de los varios bloques, respectivamente, y 0–1′, 1′–2′, 2′–3′, 3′–4′, etc., horizontalmente, para representar las presiones del agua contra dichos bloques, respectivamente; y trácese 1′–1, 2′–2, 3′–3, 4′–4, etc., representando, en intensidad y en dirección, as presiones totales inclinadas sobre las juntas 1–2, 2–3, 3–4, etc., y sobre la base, respectivamente. Así, 2′–2 representa la resultante de la presión del agua (véase Hidrostática) sobre los bloques 1 y 2 y el peso combinado de esos bloques. Desde los puntos $o_1$, $o_2$, etc., fig. 122 (*c*), donde se encuentran esas dos fuerzas en cada caso, trácense $o_1r_1$, $o_2r_2$, etc., paralelas, respectivamente, á 1′–1, 2′–2, etc., fig. 122 (*b*), hasta la junta correspondiente. Así obtenemos puntos, $r_1 \ldots r_7$, de la línea de resistencia para el caso en que la presa se llene á la profundidad supuesta. Lo que precede se refiere al diagrama para una presa ya diseñada. Al diseñar, empezamos por supuesto por arriba y trazamos las líneas 0–1, 0–1′ y 1′–1 en la fig. (*b*) para el primer bloque; luego las líneas 1–2, 1′–2′, y 2′–2, para el segundo bloque, y así sucesivamente; haciendo los cambios necesarios, como en el § 277.

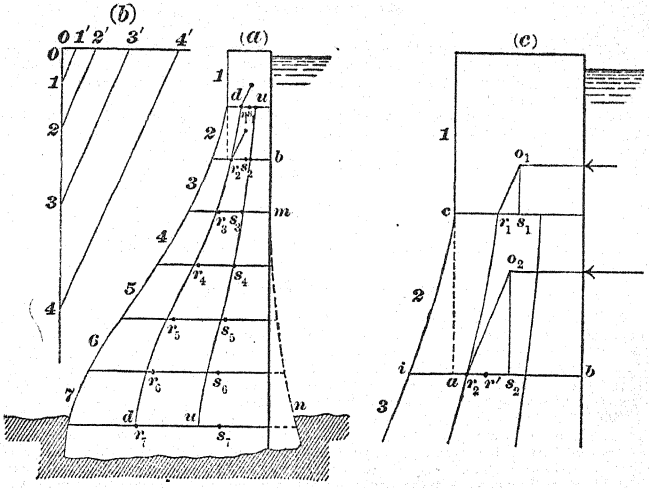

**Fig. 122.**

**279.** A fin de que la línea de resistencia, $r_1 \ldots r_7$ para la presa llena, pueda caer bien dentro de la tercera media es necesario á veces adoptar una sección transversal algo pesada; pero en vista del inminente peligro que implica la más pequeña apertura del lado de las aguas (véase § 281), es bueno aquí inclinarse del lado seguro.

**280.** A medida que este procedimiento se lleva más hacia abajo, el ángulo formado entre la cara exterior y la vertical, se hace considerable; y la tercera media, en cada una de las juntas inferiores, se va alejando más del paramento interior. Los centros de presión, $s_1 \ldots s_7$, para presa vacía, pueden pues caer más acá de la tercera media, del lado del agua, como se indica en las juntas 5–6 y 6–7. Para obviar esto, se le da á veces un perfil curvo á la cara interior, como en *mn*.

## Advertencias prácticas.

**281. La adopción de condiciones ideales** es particularmente peligrosa en el caso de presas de mampostería. Así, cualquier compresión del material sobre la cara exterior puede abrir grietas en la cara interior; y el agua, entrando en estas

grietas, ejercerá una acción semejante á la de una cuña, empujando la línea de resistencia hacia afuera, aumentando así la tendencia á la trituración del lado afuera y la formación de nuevas grietas en la cara interior. Además, si se han dejado algunas juntas relativamente blandas, el agua, penetrando así en la presa ó debajo de ella, aumenta la tendencia á resbalar, disminuyendo no sólo el peso efectivo de las porciones superiores, sino también obrando como lubricante en la junta donde penetra.

Hase insinuado que algunos defectos de las presas pueden haber sido ocasionados, en parte, á lo menos, por el vacío formado enfrente de la cara exterior entre la lámina de agua que cae y dicha cara.

**282.** Teóricamente, las curvaturas de arcos, presas, y otras construcciones compuestas de bloques, pueden hallarse por medio de las fórmulas de los §§ 162–167 del capítulo Armaduras; pero, á causa de la incertidumbre en cuanto á los valores de los coeficientes de elasticidad, E, de las piedras de construcción y de la mezcla, y á causa de la relativa inexactitud del acabado en obras de albañilería, las fórmulas son de poco valor práctico en tales casos.

## EL TORNILLO

**283.** El tornillo es un plano en espiral. « La potencia » describe una espiral, al extremo de un brazo de palanca, mientras la resistencia (ó « peso ») se mueve á lo largo del eje del tornillo. Durante el tiempo en que la fuerza hace una revolución, la resistencia recorre el « paso » del tornillo.

**284.** En consecuencia, si P=potencia, $w$=peso, $d$=paso, $l$=brazo de palanca, $v$=velocidad rectilínea del peso, y V=velocidad circular de la potencia, tenemos, teóricamente *:

$$\frac{w}{\mathrm{P}} = \frac{\mathrm{V}}{v} = \frac{2\pi l}{d}.$$

## FUERZAS QUE OBRAN SOBRE VIGAS Y ARMADURAS

### Condiciones de equilibrio.

**285.** Para el equilibrio, en vigas y armaduras es necesario y suficiente que las fuerzas resistentes, ejercidas por el material de la construcción y los momentos de esas fuerzas contrarresten las fuerzas externas ó destructivas y sus momentos. Aquí estudiamos principalmente las fuerzas destructivas. Para las fuerzas resistentes, véanse Resistencias, en capítulo Armaduras; y Vigas ó Resistencia transversal, en capítulo Resistencia de Materiales.

**286.** Las fuerzas destructivas son (1) los pesos sobre la construcción, inclusive su propio peso, cargas « vivas » ó movibles, como viento, etc., y (2) las reacciones de los apoyos. Aquí discutiremos la acción de los pesos verticales solamente, inclusive (*a*) el peso muerto, ó el peso de la construcción misma; junto con el de la calzada, etc., y (*b*) el peso vivo movible ó extraño de vehículos, trenes, personas, etc. La acción de los pesos ó cargas horizontales (viento, fuerza centrífuga, etc.), se rige por leyes semejantes y se discute en Armaduras.

**287.** Sea la fig. 123 (*a*) un *cantilever* ** que descanse en un opoyo, *b*, y lleve un peso, W, en su extremo exterior *a*. Se impide que el *cantilever* gire alrededor de *b* por la tensión T, de una cadena horizontal y por la compresión C, en un puntal horizontal***. Despreciando el peso del cantilever mismo éste está solicitado por cuatro

---

* Despreciando la fricción, que, sin embargo, modifica mucho el resultado.

** Conservamos el término *cantilever*, porque, además de no tener equivalente en español, ya está muy usado en construcción. Los términos *can*, *canecillo*, ó consola, no lo traducen como lo han creído algunos. (*N. del T.*).

*** En las figs. 123 á 127 inclusive, y las figs. 132 y 133, que muestran *cantilevers*, vigas y partes de vigas solicitadas por pesos, por reacciones, por tracciones de cadenas y empujes de postes, las flechas indican fuerzas que obran *en el cantilever ó viga ó en sus segmentos*, y no fuerzas que obran sobre el peso, los soportes, las cadenas conectadoras ó postes. Así, la tensión en una cadena tiende á *juntar* los dos cuerpos que une. En consecuencia, en estos casos, las correspondientes flechas se señalan una á otra. Por otra parte, la compresión en un puntal tiende á separar los dos cuerpos entre los cuales obra. De aquí que sus dos echas aparezcan alejándose una de otra.

fuerzas externas, que forman dos pares; un par que consta de dos fuerzas verticales á saber: el peso, W, y la reacción, R', del apoyo; el otro par que consta de dos fuerzas horizontales, á saber: la tensión T, cerca del tope, y la compresión C, cerca

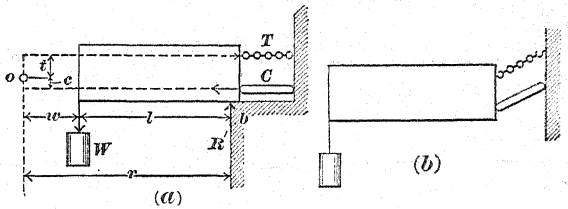

**Fig. 123.**

de la parte inferior. Si no fuera por la reacción, R', del soporte, *b*, el peso, W, empujaría el cantilever hacia abajo, como se indica en la figura 123 (*b*).

**288.** En la fig. 123 (*a*) tenemos:

Suma algebraica de fuerzas verticales $= R' - W = 0$;
— — — horizontales $= T - C = 0$;
— — momentos respecto de cualquier punto, como *o*,

$$W \cdot w - R' \cdot r + T \cdot t + C \cdot c = 0.$$

**289.** Si, como en la fig. 124, las fuerzas horizontales son ejercidas en el extremo distante del apoyo, y á la misma distancia que antes, sus intensidades y sentidos deben permanecer respectivamente los mismos; pero ahora tenemos la compre-

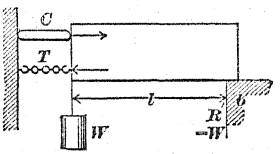

**Fig. 124.**

sión C, en lo alto, y la tensión T por debajo. Ahora, si la fig. 123 se invierte; R' obra como el peso, y W, como la reacción hacia arriba; y tenemos, como en la fig. 124, compresión, C, arriba, y tensión T abajo. Así, la fig. 124 es prácticamente la fig. 123 invertida.

**290.** La condición descrita en el § 289, fig. 124, representa también la condición en cada segmento, A, B, de una viga, figs. 125 (*a*) y (*b*) ó figs. 126 (*a*) y (*b*), sostenida en ambos extremos y llevando un peso concentrado W+W, fig. 125, ó W+*w*, fig. 126.

**291.** Supongamos la viga, fig. 125 (*a*), ó fig. 126 (*a*), dividida en dos *cantilevers* ó vigas parciales, como en la fig. 125 (*b*) ó la fig. 126 (*b*), sosteniendo cada parte

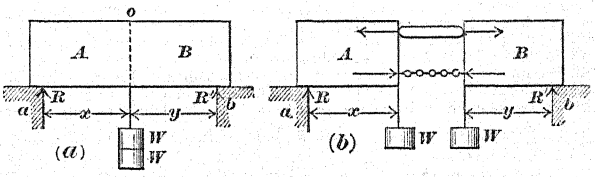

**Fig. 125.**

en su extremo, una parte del peso original. (Véase § 292.) Los esfuerzos en el pun-

tal y la cadena, figs. (*b*), reemplazan los esfuerzos del material (situado en la línea de puntos) del *cantilever* ó viga, figs, (*a*) En una armadura, estas fuerzas son ejercidas por las cuerdas; en una viga, por las particulas ó fibras en toda la sección.

**292.** Si, como en la fig. 125 (*a*), el peso está en el centro de la abertura, las longitudes, $x$ é $y$, de los *cantilevers*, fig. 125 (*b*), son iguales, como lo son también los pesos W = W, que sostienen. Pero si, como en la fig, 126 (*a*), la carga, W + *w*,

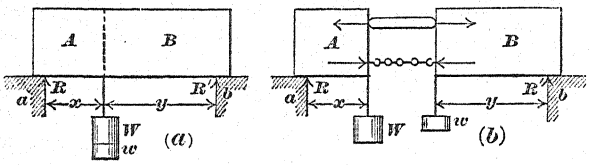

**Fig. 126.**

en la viga no está en el centro de la luz, los pesos parciales W y *w*, que se suponen sostenidos en los extremos de las dos vigas parciales, respectivamente, fig. 126 (*b*), son desiguales, é inversamente proporcionales á los brazos de palanca de sus respectivos apoyos. De aquí que los momentos de los dos pares opuestos son iguales. La reacción de cada apoyo es igual al peso cargado por el *cantilever* que descansa sobre aquél.

## Reacciones de los extremos.

**293.** Si en un *cantilever*, fig. 127, no hay sino un apoyo vertical, la reacción, R', de ese apoyo, es = la suma de todos los pesos, inclusive el peso del *cantilever* mismo; y la reacción debida á cada peso parcial es = á dicho peso parcial. Así si B = peso del *cantilever*,

$$R = W + w + B.$$

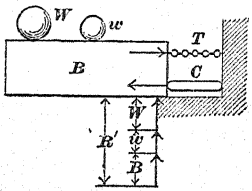

**Fig. 127.**

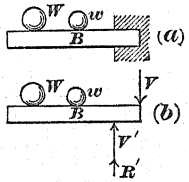

**Fig. 128.**

**294.** La reacción, R', no debe confundirse con otras fuerzas verticales. Así, un *cantilever* está á menudo sostenido como en la fig. 128 (*a*). El par, compuesto de dos fuerzas horizontales T y C, fig. 127, está reemplazado entonces por un par compuesto de dos fuerzas verticales, V y V', fig. 128 (*b*); una de las cuales, V', coincide con la reacción, R'. Aquí, R' + V', que obran hacia arriba forman la antiresultante de W, *w*, B y V que obran hacia abajo.

**295.** En una viga, fig. 129, la suma de las dos reacciones de los extremos es = la suma de todos los pesos, inclusive el peso de la viga misma.

**296.** La reacción, R, del apoyo izquierdo, *a*, fig. 129, debida al peso W, solo es $R = W \cdot \frac{y}{l}$ (véase § 17), y la reacción, R', del soporte derecho, *b*, es $= W - R = W \cdot \frac{x}{l}$. Si el peso es central, $\frac{x}{l} = \frac{y}{l} = \frac{1}{2}$. y $R = R' = \frac{W}{2}$.

**297.** Gráficamente, la fig. 156 supone un peso concentrado, W (no mostrado), que ha de colocarse en la viga en cualquier punto, como *c*. Trácese *a'a''* y *b'b''*,

verticales y cada una = W. Unanse $a''b'$, y, $a'b''$, y trácese $gh$, verticalmente por $c$. Entonces la ordenada, $c'g$, á la línea superior, $a''b'$, y la ordenada, $c'h$, á la línea

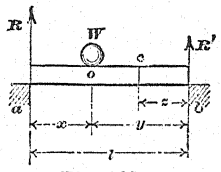

Fig 129.

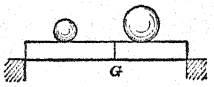

Fig. 130.

inferior, $a'b''$, dan las reacciones del extremo de la izquierda y del de la derecha, R y R', respectivamente.

**298.** Cuando, como en la fig. 130, hay dos ó más pesos (en que el peso de la viga puede ó no estar incluído). las reacciones debidas á cada peso ó carga pueden obtenerse separadamente, dando las sumas de estas reacciones, las reacciones totales; ó encuéntrese primero el centro común de gravedad, G, de todos los pesos (véanse §§ 125, etc.), y luego calcúlese la reacción como para un solo peso, W, fig. 129; todos los pesos elementales combinados cuyo centro de gravedad está en G, se suponen concentrados allí.

**299.** En una viga, fig. 131, sometida á un peso, W, uniformemente distribuído sobre cualquier parte de la luz, sea G el centro de gravedad del peso, y sean $x$ é $y$ los segmentos de la luz, $l$, á la izquierda y derecha de G respectivamente.

Luego, despreciando el peso de la viga, $R = W\frac{y}{l}$; y $R' = W - R = W\frac{x}{l}$.

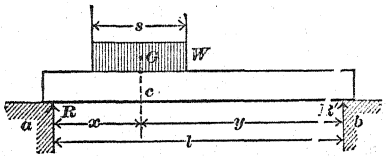

Fig. 131.

**300.** Si el peso está uniformemente distribuído sobre toda la abertura ó luz su centro de gravedad está en el centro de la abertura y tenemos :

$$\frac{x}{l} = \frac{y}{l} = \frac{1}{2}; \quad \text{y } R = R' = \frac{W}{2}.$$

## Momentos y esfuerzo cortante.

**301.** A fin de determinar qué fuerzas internas se requieren, en cualquier punto de la abertura ó luz, para el equilibrio, podemos suponer que el *cantilever* ó la viga está cortado en dos por una sección, *cc*, figs. 132 ó 133, en dicho punto, é inquirir qué fuerzas deben aplicarse, en la sección, para mantener en equilibrio los dos segmentos, E y F, en que la sección, *cc*, divide la luz, fig. 132, ó esa parte de la abertura entre el peso y un soporte, fig. 133. Las fuerzas, así determinadas, son con evidencia equivalentes á las realmente ejercidas con el mismo fin, por la viga misma

**302.** En las figs. 132 y 133, los momentos de los pesos y de las reacciones, ó los momentos externos ó de flexión, están indicados por flechas, *por debajo* del *cantilever* y de la viga respectivamente, mientras que los momentos resistentes de las fuerzas internas están indicados por flechas *dentro* de dichos cuerpos.

**303.** *En el cantilever*, fig. 132, el peso, $w = 4$ lbs, distante 6 p de la sección, *cc*, produce allí un momento izquierdo ó negativo de $6 w = 6 \times 4 = 24$ p-lbs. Por tanto, para el equilibrio, el puntal horizontal y la cadena, en *cc*, deben ejercer un momento

resistente á la derecha ó positivo, de 24 p-lbs; y, estando á 2 pies de distancia, deben ejercer una tensión, T, y una compresión, C, de $\frac{24}{2} = 12$ lbs cada uno. En el apoyo, el momento del peso $= 9\ w = 9 \times 4 = 36$ p-lbs; y $T' = C' = \frac{36}{2} = 18$ lbs *.

**304.** Pero, considerando sólo las fuerzas hasta ahora discutidas, encontramos en el segmento derecho, F, obrando en *cc*, un par izquierdo, $= d \times T = d \times C = 2 \times 12 = 24$ p-lbs; y en el apoyo, un par derecho, $= d \times T' = d \times C' = 2 \times 18 = 36$ p-lbs.

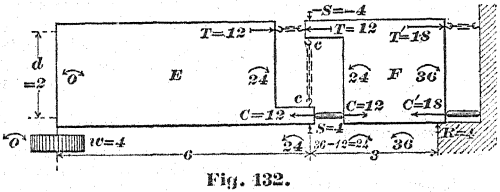

Fig. 132.

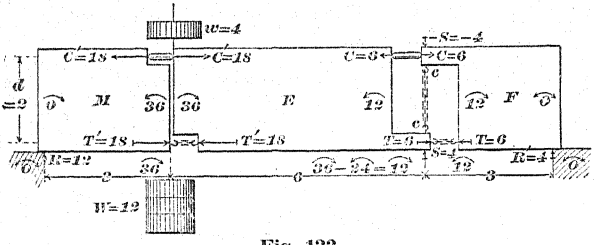

Fig. 133.

En otros términos, habría un exceso no equilibrado de momento derecho, $= 36 - 24 = 3$ R′$= 3 \times 4 = 12$ p-lbs, obrando sobre F. F recibe también, en el apoyo, la reacción hacia arriba R′, $= 4$ lbs, de ese apoyo. De manera semejante, el par, $d \times T = d \times C$, en *cc*, ejerce, en el segmento izquierdo, E, un momento derecho aparentemente no equilibrado de $2 \times 12 = 6\ w = 6 \times 4 = 24$ p-lbs, y E recibe, del peso *w*, un empuje hacia abajo $= 4$ lbs.

**305.** Para el equilibrio, por tanto, la cadena vertical en *cc* debe ejercer una tensión $= S = w = R' = 4$ lbs, que empuje á F hacia abajo y á E hacia arriba. La tensión hacia abajo — S, obrando sobre F en *cc*, forma, con la reacción, R′, del soporte, un par izquierdo $= 3$ R′$= 3 \times 4 = 12$ p-lbs, equilibrando el exceso de momento derecho que obra sobre F; mientras que la tensión hacia arriba, +S, que obra sobre E en *cc*, forma, con el peso, *w*, un par izquierdo $= 6w = 6 \times 4 = 24$ p-lbs, equilibrando el exceso de momento derecho, que obra sobre E.

**306.** De modo semejante, si suponemos el *cantilever* cortado por una sección en cualquier otro punto, hallaremos que se requiere una fuerza vertical $= S = w = R'$, obrando hacia arriba sobre el segmento izquierdo y hacia abajo sobre el segmento derecho, á fin de mantener el equilibrio y transmitir el peso, *w*, al apoyo, de modo que los dos segmentos puedan obrar unidos como un solo *cantilever*. Esta fuerza, S es llamada esfuerzo cortante. Véanse §§ 325, etc. Sin ella, la sección E caería, como en la fig. 123 (*b*).

**307. En la viga**, fig. 133, el peso total es 16 lbs; y sus distancias, 3 p y 9 p, desde el soporte izquierdo y derecho respectivamente, estando como 1 á 3, las

* *N. del T.* — Empleando el kilogramo como unidad de peso, y el metro para las distancias, los momentos vendrían en kilogramos × metros; es decir, en *kilogrametros* y no en pies-lbs. Pero como para la comprensión de la teoría en nada influye este cambio hemos dejado las medidas inglesas. Así vamos de acuerdo con los números (interiores) de los clisés.

reacciones de los extremos (§§ 293, etc.) estarán como 3 á 1; ó, $R = 16 \times \frac{3}{4} = 12$ lbs; $R' = 16 \times \frac{1}{4} = 4$ lbs. Nosotros consideramos, por tanto, la viga como cortada por una sección donde está el peso (lo mismo que en *cc*), y el peso total de 16 lbs como dividido en dos porciones; una, $W = R = 12$ lbs, inherente al segmento del extremo M; y la otra $w = R' = 4$ lbs sostenida por el segmento medio, E. Aquí, como en la fig. 132, los segmentos E y F juntos forman un *cantilever* de 9 p de largo, cargado con un peso, *w*, de 4 lbs, en su extremo; pero, en la fig. 133, las fuerzas resistentes horizontales, T' y C', que sostienen el *cantilever* entero (E+F), están ejercidas, no en el apoyo, como en la fig. 132, sino en el extremo más distante del apoyo.

**308.** Tenemos, en consecuencia, en la fig. 133, momentos positivos * (*como el del minutero*) y negativos (contra el del minutero), obrando sobre E, cerca del extremo inferior de *cc*, así :

$$dC' - 6w - dC = 2 \times 18 - 6 \times 4 - 2 \times 6 = 0.$$

Aquí, $dC' - 6w = 36 - 24 = 12$, es momento de flexión, y $(-dC, = -12)$, es momento resistente.

Tenemos, también, en *cc* el esfuerzo cortante, $S = w = R' = 4$ lbs.

**309.** En la fig. 132 ó en la fig. 133, considerando que el segmento se extienda desde el peso á uno ú otro apoyo (en la fig. 132 no hay sino un solo segmento), se verá que, en el extremo libre de cualquier segmento semejante, las fuerzas horizontales son cero, y que ellas aumentan uniformemente hasta un máximum en el otro extremo del segmento. Así, en la fig. 132, aumentan uniformemente desde 0, en el extremo cargado ó libre, hasta 18 lbs en el apoyo; mientras, que en la fig. 133, aumentan uniformemente desde 0, en cada apoyo, ó extremo libre, hasta 18 lbs, en la carga.

**Momentos en los cantilevers.** (Véanse también §§ 285, etc., pág. 458.)

**310.** En un *cantilever*, fig. 134, cada peso ejerce, sobre cualquier punto situado entre él y el apoyo, un momento = su peso × la distancia horizontal de su centro de gravedad á dicho punto; y el momento total, respecto á cualquier punto, es la suma de los momentos de los varios pesos respecto á ese punto. Así, despreciando el peso del *cantilever* mismo, tenemos :

respecto al punto *b*, momento $= Ax + By$; respecto á *d*, momento $= Az$; para *c*, momento $= Am + Bn$; para A, ó cualquier punto más allá de A, momento $= 0$.

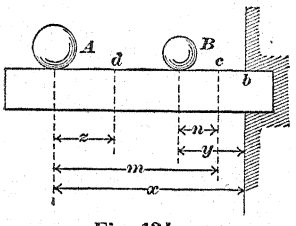

**Fig. 134.**

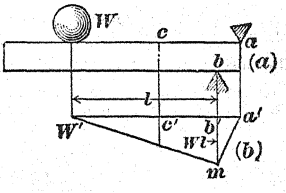

**Fig. 135.**

**311.** En un *cantilever*, fig. 135, la palanca máxima de cualquier peso W, es evidentemente su distancia, *l*, al apoyo, *b*. De aquí, que el momento de flexión

---

* *N. del T.* — Cuando el movimiento rotatorio engendrado por un par en un plano visto de frente, se efectúa de *izquierda á derecha pasando por arriba*, precisamente como se mueven las manecillas de un reloj, lo llaman los ingleses *clockwise*; es decir: « á modo del reloj »; y al movimiento contrario, *counterclockwise*; es decir: « contra el modo del reloj ». Además extienden estos nombres á la sola tendencia del movimiento en dichos sentidos y aun al par y á su momento; considerando además á los primeros, como positivos, y á los segundos, como negativos. En el deseo de enriquecer la terminología española en el ramo de ingeniería, donde no abundan los términos de la sintética claridad y expresión de éstos, hemos resuelto emplear en lugar del *clockwise*, « *como el del minutero* », y en lugar del *counterclockwise*, « *contra el minutero* », ya que sería muy largo decir: « en el sentido del de las agujas de un reloj » y « en sentido contrario al de las agujas de un reloj ».

máximo de cualquier peso en un *cantilever* está en el apoyo, y es=W*l*. De este máximo, el momento disminuye uniformemente hasta 0 en el peso y en *a*.

En la fig. 134, el extremo, *ba*, está uniformemente cargado, y la disminución del momento, entre *b* y *a* sigue las ordenadas de una parábola, como en *mk'*, fig. 137.

**311 a.** En los *cantilevers* y vigas, figs. 129 y 134, los momentos (como el del minutero) * de las fuerzas á *la izquierda* de un punto dado, *c*, se consideran *positivos*, y viceversa. Los momentos *positivos extienden* las fibras *inferiores* y *comprimen* las *superiores*, y viceversa.

**312.** En la fig. 135 (*b*), (*cantilever* con un solo peso, W), trácese por una escala *b'm*, =mom máx y trácense *m*W' y *ma'*. Entonces, para cualquier punto, *c*, el momento=á la ordenada en *c'* respecto á la línea *m*W'.

**313.** En un *cantilever*, fig. 136 (*a*), con dos ó más pesos concentrados, W y *w*, sean :

*b'm*, fig. 136 (*b*), =momento de W, en el apoyo;
*b'm'*, fig. 136 (*b*), =momento de *w*, en el apoyo.

Entonces, para ambos pesos, W y *w*, (despreciando el peso de la viga),

en *d*, momento= de W solo, =ordenada en *d'*;
en *c*, momento=suma de los momentos de W y *w*,
=suma de las dos ordenadas, *c'n* y *c'n'* en *c'*.

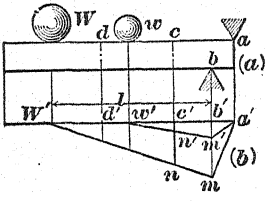

**Fig. 136.**

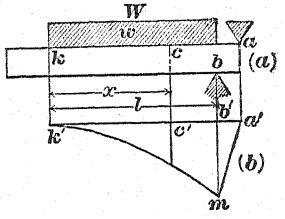

**Fig. 137.**

**314.** En un *cantilever*, fig. 137 (*a*), bajo un peso, W, uniformemente distribuído sobre una longitud, *l*, que empieza en el apoyo, *b*, el momento máximo, en el soporte *b*, es=W*l*/2.

En la fig. 137 (*b*) hágase *b'm*=dicho momento máximo y trácese una semiparábola *mk'*, con el vértice en *k'*. Luego, en cualquier otra sección, *c*, el momento está representado por la ordenada *c'* de dicha parábola, y es=$w \times \frac{x}{2}$, donde *w*=el peso de esa parte de W más allá de *c*, y *x*=el largo de dicha parte.

En *k*, ó en cualquier punto más allá de *k*, el momento=0.

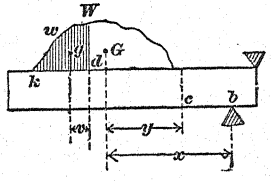

**Fig. 138.**

**315.** En la fig. 138, despreciando el peso del *cantilever* mismo, sea W el peso de toda la carga, y *w* el de la parte sombreada, concentrados en sus respectivos centros de gravedad G y *g*. Entonces,

respecto al punto *b*, el momento=W . *x*;
— — *c*, — =W . *y*;
— — *d*, — =*w* . *v*;
— — *k*, ó cualquier punto más allá de *k*, el momento=0.

* *N. del T.* — Véase la *N. del T.* al pie de la página 463.

## Momentos en las vigas.

**316.** En una viga, fig. 129, la reacción hacia arriba que cada apoyo ejerce, da para cualquier punto un momento = reacción × distancia de dicho punto al apoyo; pero cualquier peso, entre el punto elegido y el apoyo, ejerce un momento contrario = peso × distancia del peso al punto. Así,

$$\text{para } c, \text{ momento} = R' \,.\, z = R\,(l - z) - W\,(y - z).$$

En cada apoyo, el momento es 0.

**317.** En una viga, fig. 129, cargada con un solo peso concentrado, W, el momento, $R' \,.\, z$, en cualquier punto, $c$, es $= R' \,.\, z = W\,\frac{x}{l} \,.\, z = R\,(l - z) - W\,(y - z) = W \,.\, \frac{y}{l}\,(l - z) - W\,(y - z)$. En un punto, como $c$, que no está bajo el peso, el momento, $R'z$, es evidentemente menor que el momento, $R' \,.\, y$, para el punto $o$, bajo el peso. En otras palabras, el momento máximo está en el punto, $o$, debajo del peso.

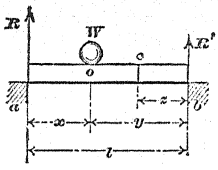

**Fig. 129 (repetida).**

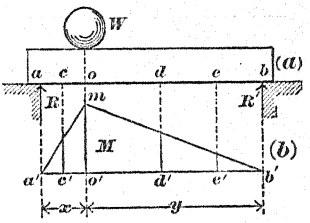

**Fig. 139.**

**318.** Desde el punto, $o'$, fig. 139 ($b$), correspondiente al punto, $o$, fig. ($a$), donde se aplica el peso, levántese una ordenada, $o'm$, igual por escala al momento (máximo), $= R' \,.\, y = R \,.\, x$, en ese punto. Unase $a'mb'$. Entonces las ordenadas hacia $a'm$, ó hacia $mb'$, en cualesquiera puntos, $c'$, $d'$, $e'$, etc., representan por escala el momento para el punto correspondiente, $c$, $d$, $e$, etc., en la luz.

**319.** Cuando el peso, W, está en el centro de la abertura, $l$, fig. 140, la reacción en cada extremo es $= \frac{W}{2}$. En consecuencia, el momento $s'$, en cualquier punto, $s$; distante $y$ de un apoyo, $b$, es $= \frac{W}{2} \,.\, y$.

En el centro de la luz (es decir, en el punto, bajo el peso central, W), tenemos:

$$\text{momento máximo, } M, = \frac{W}{2} \cdot \frac{l}{2} = \frac{W \,.\, l}{4}$$

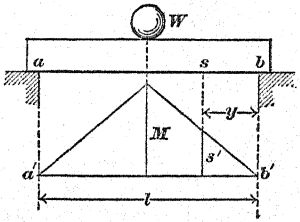

**Fig. 140.**

A fin de que el momento máximo (en $o$, fig. 139) debido á un peso excéntrico, W,

sea igual al momento máximo (en el centro de la luz, $l$) debido á un peso dado C en el centro debemos tener

$$W\frac{x}{l}\cdot y = C\cdot\frac{l}{4}; \quad \text{ó bien } W = C\frac{l}{4}\cdot\frac{l}{xy} = C\frac{\left(\frac{l}{2}\right)^2}{xy}$$

**320.** Cuando hay dos ó más pesos concentrados, $c$, $d$, $e$, fig. 141, trátese cada peso como en la fig. 139, haciendo que cada ordenada corta $m$, $m'$, $m''$, represente el momento máximo de su peso, $c$, $d$, ó $e$ solo. Háganse las ordenadas largas, M, M' y M''=las sumas de los momentos separados, medidos en $c'$, en $d'$ y en $e'$, respectivamente. Luego las ordenadas hacia $a'$ MM'M''$b'$, en cualquier punto, representan el momento total en ese punto, debido á los varios pesos combinados.

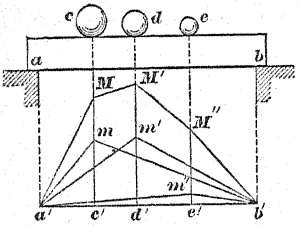

**Fig. 141.**

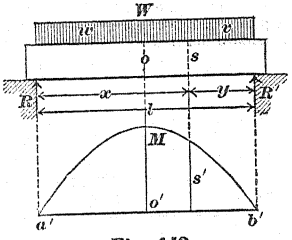

**Fig. 142.**

**321.** En una viga, fig. 142, bajo un peso uniforme, W, que cubra la luz, $l$, el momento máximo está en el centro, y es=

$$R\cdot\frac{l}{2} - \frac{W}{2}\cdot\frac{l}{4} = \frac{W}{2}\cdot\frac{l}{2} - \frac{W}{2}\cdot\frac{l}{4} = \frac{W}{2}\cdot\frac{l}{4} = \frac{W.l}{8}.$$

Hágase o'M, por escala=al momento máximo; y trácese la parábola $a'Mb'$, con el vértice en M. Entonces el momento, en cualquier sección, como $s$, está representado por la ordenada correspondiente, $s'$, á esa parábola.

Sean $w$ y $v$=á las partes de W á la izquierda y derecha de $s$, respectivamente. Entonces, momento en $s = \frac{w}{2}y^* = \frac{v}{2}x^* = \frac{1}{2}$ del momento debido á todo el peso W, concentrado en $s$*.

En uno ú otro apoyo el momento=0.

En la fig. 131, en un punto, $c$, bajo el centro de gravedad de un peso W, uniformemente distribuído sobre una porción, $s$, de la luz, despreciando el peso de la viga, se tiene :

$$\text{momento} = R\cdot x - \frac{W}{2}\cdot\frac{s}{4} = R\cdot x - \frac{W\cdot s}{8} = R'\cdot y - \frac{W\cdot s}{8}.$$

---

* Momento en $s = R'y - v\frac{y}{2} = \frac{W}{2}y - \frac{v}{2}y = \frac{W-v}{2}y = \frac{w}{2}y$; $= Rx - w\frac{x}{2} = \frac{W}{2}x - \frac{w}{2}x = \frac{W-w}{2}x = \frac{v}{2}x$.

Con W concentrado en $s$,

$$\text{momento en } s = W\frac{x}{l}y = wy = W\frac{y}{l}x = vx.$$

**322.** Sean W = al peso total, concentrado ó uniforme, y $l$=la luz. Entonces el momento máximo, M, es el siguiente:

| | | | | |
|---|---|---|---|---|
| *Cantilever.* | Peso, W, en el extremo. | M en el apoyo | | $M = Wl$; |
| — | — uniforme. | — | — | $M = \frac{Wl}{2}$; |
| Viga apoyada †. | — en el centro. | M en el centro | | $M = \frac{Wl}{4}$; |
| — — | — uniforme. | — | — | $M = \frac{Wl}{8}$; |
| Viga fija ‡. | — en el centro. | — | — ó apoyo | $M = \frac{Wl}{8}$; |
| — — | — uniforme. | — | apoyo | $M = \frac{Wl}{12}$. |

**323.** En la viga inclinada, fig. 143, para encontrar las reacciones pueden usarse las distancias inclinadas en vez de las distancias horizontales. Así,

$$\text{Reacción } R' = W \cdot \frac{x}{l} = W \cdot \frac{x'}{l'}.$$

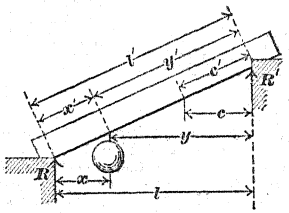

**Fig. 143.**

Pero, para encontrar los momentos de las fuerzas verticales, debemos por supuesto usar las distancias horizontales, no las inclinadas. Así, para $c$ el momento es R'$c$; no, R'$c'$.

**324.** En las vigas curvas se aplican los mismos principios que en las vigas rectas. Así, fig. 144, en $s$, el momento=W . $l$. En la fig. 145 (*a*), la reacción $R' = \frac{W \cdot x}{l}$, y en $s$, momento=R' . $y$. O, como en la fig. 145 (*b*), desde $o$, donde

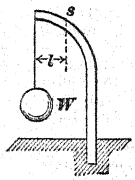

**Fig. 144.**

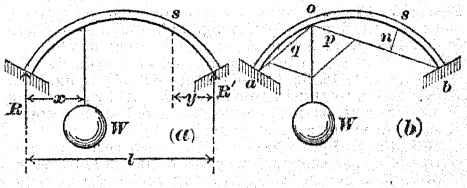

**Fig. 145.**

se aplica el peso, trácese *oa* y *ob* hasta los dos apoyos respectivamente, y, por medio del paralelogramo de las fuerzas, encuéntrense las componentes, $p$ y $q$, de W. Entonces el momento en $s$=$p$ . $n$.

† Viga apoyada en cada extremo, pero fija.
‡ Viga fijada en cada extremo.

## Esfuerzo cortante.

**325.** En la viga, *ab*, fig. 146 (*a*), considérense los segmentos, *ac* y *cb*, á la izquierda y á la derecha respectivamente del plano *nn*. Además de las fuerzas horizontales que obran al través del plano *nn*, hemos visto (§ 305) que necesitamos también, para el equilibrio, una fuerza vertical = á la reacción del extremo izquierdo, R, que obre hacia abajo sobre el segmento izquierdo *ac* y forme un par con R; y que, al mismo tiempo, obre hacia arriba sobre el segmento derecho, *cb*, y sea = al peso, W, menos la reacción del extremo derecho, R'. Esta fuerza es el esfuerzo cortante, S, en la sección *nn*. Puede considerársela como la transmisión de las fuerzas verticales de los pesos á los apoyos ó viceversa.

**326.** Los dos segmentos, *ac* y *cb*, tienden así á separarse verticalmente por la sección *nn*, tendiendo el segmento derecho, *cb*, á bajar, á causa de la preponderancia del peso, W, sobre la reacción del extremo derecho, R'; y á esta tendencia la resiste el esfuerzo cortante, *s*, que es = á la reacción del extremo izquierdo, R. La misma tendencia existe uniformemente entre W y *a*, y en todas partes la equilibra el esfuerzo cortante = S = R.

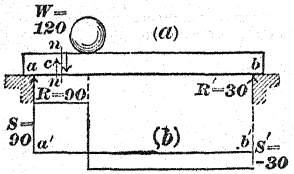

Fig. 146.

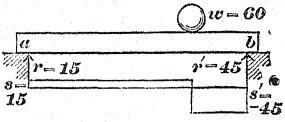

Fig. 147.

**327.** Entre el peso, W, y el apoyo derecho, *b*, también existe esfuerzo cortante uniforme; pero aquí el esf cort S' = á la reacción del extremo derecho, R' = R — W; y, mientras que dicho esfuerzo cortante, S, á la *izquierda* del peso era *derecho, como el del minutero* (véase *N. del T.*, pág. 463) (recibiendo la porción á la *derecha* de cualquier sección, *nn*, la fuerza *hacia abajo*), se le considera *positivo*, ó +; el esfuerzo á la derecha del peso es *izquierdo, contra el minutero* (recibiendo la porción á la *izquierda* de cualquier sección la fuerza *hacia abajo*), y se le considera *negativo*, ó —.

**328.** Los esfuerzos cortantes, S y S', á la izquierda y á la derecha del peso, W, están representados, en la fig. 146 (*b*), donde S, á la izquierda del peso, está trazado por encima de la línea cero que es la *a'b'*, para indicar un esfuerzo cortante *positivo*, y viceversa.

**329.** Comparando las figs. 146, 147 y 148, nótese que entre el apoyo izquierdo, *a*, y el peso W, fig. 146, tenemos esfuerzos cortantes positivos, S = 90, fig. 146, y *s* = 15, fig. 147; de modo que, en la fig. 148, donde *ambos* pesos, W y *w*, están sobre la misma viga, tenemos, entre *a* y W, un esfuerzo positivo total de S + *s* = 90 + 15 = 105. Entre el apoyo derecho, *b*, y el peso *w*, fig. 147, tenemos esfuerzo negativo S' = — 30, fig. 146, y *s'* = — 45, fig. 147; de modo que, en la fig. 148, entre *b* y *w*, tenemos un esfuerzo total negativo = S' + *s'* = — 30 — 45 = — 75. Pero, entre los puntos de aplicación de W y *w*, tenemos S' = — 30, fig. 146, y *s* = + 15, fig. 147; dejando, entre W y *w*, fig. 148, *s* + S' = 15 — 30 = — 15. Si la reacción total del extremo derecho, R' + *r'*, excede *w*, como aquí suponemos, el esfuerzo cort, en cualquier punto entre los dos pesos, W y *w*, fig. 148, es negativo, como se indica, y viceversa.

**330.** En cualquier sección el esfuerzo cortante = á la reacción en cualquier extremo, menos cualesquiera pesos entre ese extremo y la sección dada.

**331.** Si, como en la fig. 149, la reacción del extremo derecho, R' + *r'*, es = al peso, *w*, entonces, la reacción del extremo izquierdo, R + *r*, es = al peso, W; y no hay esfuerzo cortante en ningún punto entre los dos pesos. En otros términos, si se corta la viga en una sección cualquiera entre W y *w*, las fuerzas horizontales solas conservarán el equilibrio, no requiriéndose fuerzas verticales, desde que los dos segmentos no tienen tendencia á moverse verticalmente alejándose el uno del otro.

**332.** Condición semejante existe en cualquier sección en donde el signo del esfuerzo cortante cambia de + á — ó viceversa. Así, si se corta la viga en una

sección inmediatamente bajo W, fig. 146 ó 148, ó bajo *w*, fig. 147, las fuerzas horizontales equivalentes á las resistencias de las fibras en la viga, bastarán para conservar el equilibrio, sin fuerza vertical, ó esfuerzo cortante; no habiendo tendencia de los dos segmentos á moverse verticalmente separándose uno del otro. También, cuando, como en la fig. 149, bajo W y *w*, el esfuerzo cort cambia de valor, en un lado de una sección, para hacerse cero en el otro lado. El esfuerzo cortante en la sección misma es=0.

**333.** Pero cuando, como en la sección bajo *w*, fig. 148, el esfuerzo cort cambia en intensidad sin cambiar de signo, hay un esfuerzo=al *menor* de los dos en los lados opuestos de la sección, pues éste es la intensidad del esfuerzo cortante al través de la sección; ó dicho de otro modo, la tendencia de los dos segmentos á moverse allí verticalmente alejándose uno del otro.

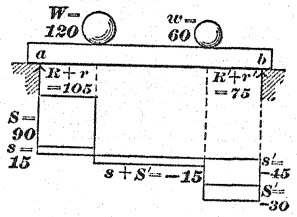

Fig. 148.

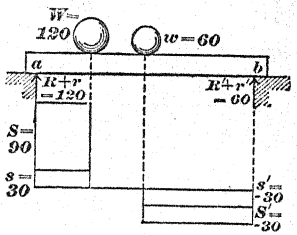

Fig. 149.

**334.** Con cualquier número de pesos, si llamamos X á la porción del peso total á la izquierda de cualquier sección, y á la porción á la derecha de la misma sección la llamamos Y, encontraremos que el esfuerzo cortante en la sección es igual á la diferencia entre la parte de X que va al apoyo derecho, *b*, y la parte de Y que va al apoyo izquierdo, *a*.

**335.** Con un peso, W, fig. 150 (*a*), uniformemente distribuído sobre la abertura toda, el esfuerzo cort máximo, $= R = R' = \frac{W}{2}$, obra en cada apoyo *a* y *b*. El mínimo esf cort=0 está, en el centro, *c*, de la abertura, centro donde está también el máximo del momento de flexión. Véanse § 321 y fig. 142.

En cualquier punto, *d*, el esfuerzo cortante está dado por la ordenada correspondiente *d'*, fig. 150 (*b*). Véase Relación entre «el momento y el esfuerzo cortante» §§ 359, etc.

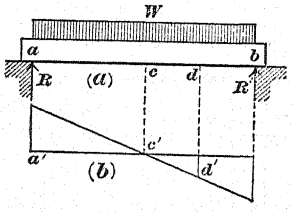

Fig. 150.

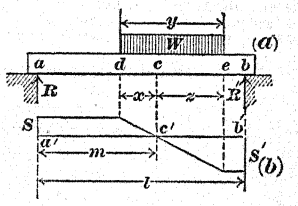

Fig. 151.

**336.** Con un peso, W, uniformemente distribuído sobre cualquier parte, *y*, de la luz, fig. 151 (*a*), encuéntrense las reacciones de los extremos, R y R', como en el § 299. Luego

entre *a* y *d*, el esfuerzo cortante=S =R;
— *e* y *b* — — =S'=R';
en *c*, — — =0;

$$x = dc = y.\frac{R}{W};\quad z = y - x = ce = y.\frac{R}{W}.$$

**337.** Cuando la parte cargada, $y$, de la luz, empieza en uno de los apoyos, $b$ fig. 152 ($a$), entonces, puesto que $R = W\frac{\frac{1}{2}y}{l} = W\frac{y}{2l}$, tenemos

$$x = dc = y.\frac{R}{W} = y\,\frac{W\frac{y}{2l}}{W} = y\,\frac{y}{2l} = \frac{y^2}{2l}.$$

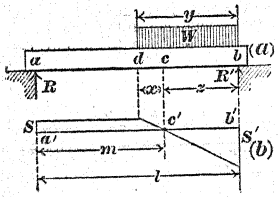

Fig. 152.

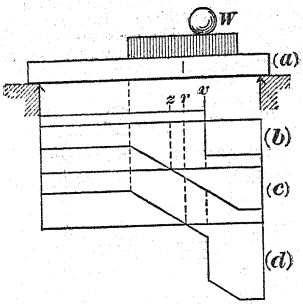

Fig. 153.

**338.** Cuando se agrega un peso concentrado, W, fig. 153, á un peso uniformemente distribuído sobre la luz ó abertura entera, ó sobre parte de ella, cada peso produce los mismos esfuerzos cortantes que si estuviese solo. Los debidos á W están representados en la fig. 153 ($b$), mientras los debidos al peso uniforme están representados en la fig. 153 ($c$). El esfuerzo cortante resultante, debido á ambos pesos combinados, está representado en la fig. 153 ($d$). Nótese que, entre $v$ y $r$, la adición de W, con su esfuerzo cortante positivo, *reduce* el *negativo* debido al peso uniforme, y que, entre $r$ y $z$, la adición de W invierte el esfuerzo negativo; también que cambia el punto cero de $z$ á $r$.

**Para vigas continuas,** véase Vigas en el capítulo « Resistencia de Materiales ».

## Diagramas de influencia.

**339.** Las reacciones de los extremos, debidas á un peso dado, y por consiguiente los momentos, efectos cortantes y tensiones, producidos, en cualquier punto dado de una abertura ó luz, por dicho peso, varían con la posición del peso respecto á los apoyos. Llámase diagrama ó línea de influencia, un diagrama, figs. 154 ($b$), 155 ($b$), 156 ($b$), que muestra los cambios así producidos para cualquier punto dado.

### Diagrama de influencia para los momentos.

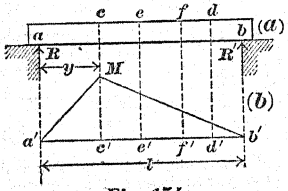

Fig. 154.

**340.** Así, en la fig. 154 ($b$), $a'Mb'$ es el diagrama de influencia de los momentos para el punto, $c$, bajo un solo peso concentrado, W *.

* Como el peso, en esta discusión, ocupa diferentes posiciones en diferentes tiempos, no se indica en la figura.

**341.** En la fig. 154, sean $l$ la luz, $x$ la distancia variable del peso, W, *, desde el apoyo derecho, $b$, é $y$ la distancia constante, $ac$, de un punto dado, $c$, al apoyo izquierdo, $a$. Entonces, para cualquier posición de W, la reacción del extremo izquierdo, R, es $= W.\frac{x}{l}$; y el momento de esa reacción para $c$ $= R.y, = W.\frac{x}{l}.y$.

La reacción del extremo derecho es $R' = W\frac{l-x}{l}$, y su momento, respecto á $c$, es

$$R'(l-y) = W\frac{l-x}{l}(l-y).$$

Mientras W esté entre $b$ y $c$, el momento, en $c$, es $= R.y = W.\frac{x}{l}y$.

**342.** Puesto que W, $y$, $l$ son constantes, el momento, en $c$, mientras W esté entre $b$ y $c$, es proporcional á la distancia variable, $x$, del peso al punto $b$. Aquél aumenta por tanto uniformemente, desde 0, cuando W está en $b$, hasta su valor máximo, M, cuando W está en $c$ mismo. Véase § 317. Por tanto, si se hace la ordenada, $c'$ M, igual, por escala, al momento máximo, M, entonces el momento, para $c$, en cualquier posición $d$, $e$, $f$, de W, entre $c$ y $b$, lo da la correspondiente ordenada, $d'$, $e'$, $f'$, á la línea $b'$M. Semejantemente, los momentos, en $c$, para cualesquiera posiciones de W entre $c$ y $a$, los dan las ordenadas á la línea $a'$M.

**343.** Para el momento, en $c$, para cualquier número de pesos, en cualesquiera posiciones, encuéntrese como arriba el momento, en $c$, para cada peso separadamente, y tómese la suma de ellos.

**344.** Es costumbre construir el diagrama de influencia para los momentos de un peso, W = unidad (1 tonelada, 1 libra, 1 mil kilogramos, etc.). Cada ordenada debe entonces multiplicarse por su correspondiente peso, medida con la correspondiente unidad, á fin de obtener el momento requerido.

**345.** Cuando W está en el punto $c$, tenemos $x = l - y$. En consecuencia, la ordenada, $c'$M = momento máximo, $= W.\frac{l-y}{l}y$; ó, si W = 1, $C'M = \frac{l-y}{l}.y$.

El área del diagrama, $a'Mb'$, es $= \frac{l}{2}.c'M = \frac{l}{2}.\frac{l-y}{l}.y = \frac{(l-y)y}{2}$.

**346.** Si un peso = 1, se distribuye sobre una longitud = 1, en $c$, fig. 155 ($a$), el momento resultante, en $c$, puede ser representado por el área del rectángulo que se halla en $c'$, fig. ($b$), siendo la altura de dicho rectángulo la ordenada, $c'$M, y su largo = 1. Así mismo, el momento, en $c$, debido á un peso uniformemente distribuído, $ef$, de 1 por unidad de longitud, fig. ($a$), puede ser representado por la suma de las áreas de los rectángulos entre $e'$ y $f'$, fig. ($b$); y, si suponemos el peso, $ef$, fig. ($a$), de 1 por unidad de long, dividido en muchas fajas verticales muy angostas, el momento resultante, en $c$, puede suponerse representado por el área del trapezoide sombreado sobre $e'f'$, fig. 155 ($b$). El momento, en $c$, debido á un peso de $p$ (lbs, tone-

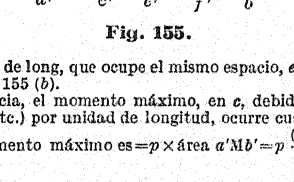

**Fig. 155.**

ladas, etc.) por unidad de long, que ocupe el mismo espacio, $ef$, es $= p \times$ área del trapezoide sobre $e'f'$, fig. 155 ($b$).

**347.** En consecuencia, el momento máximo, en $c$, debido á un peso uniforme de $p$ (lbs, toneladas, etc.) por unidad de longitud, ocurre cuando ese peso cubre la luz entera. Este momento máximo es $= p \times$ área $a'Mb' = p\frac{(l-y)y}{2}$. Véase §345.

---

* Véase nota pág. 470.

## Diagrama de influencia para el esfuerzo cortante.

**348.** Bajo un solo peso concentrado, este esfuerzo, en cualquier punto entre el peso y uno de los apoyos, es = la reacción del apoyo. Véanse §§ 326 y 327.

**349.** En el diagrama de influencia del esfuerzo cortante, fig. 156, como en el diagrama de influencia del momento, fig. 154, sea $l$ la luz; $x$ la distancia variable del peso, W, al apoyo derecho, $b$; $y$, la distancia constante, $ac$, de un punto dado, $c$, al apoyo izquierdo, $a$. Entonces, para cualquier posición de W, la reacción del extremo izquierdo, R, ó el esfuerzo cortante, S, en cualquier punto entre el peso y el soporte izquierdo, es $= W.\frac{x}{l}$; y la reacción derecha, R', ó el esfuerzo cort S', en cualquier punto entre el peso y el soporte derecho, es $= W.\frac{l-x}{l}$.

**350.** La línea de influencia del esf cort como la de los momentos, § 344, se construye de ordinario para un peso = á la unidad, de modo que $S = R = \frac{x}{l}$; y $S' = R' = \frac{l-x}{l}$. Cada ordenada del diagrama del esf cort debe entonces multiplicarse por W, para obtener el esfuerzo cortante requerido.

**351.** Puesto que W (=1) y $l$ son constantes, R y S varían directamente (y R' y S' inversamente *) con $x$. Así, cuando W (=1) está en $b$, tenemos $x=0$; $S=R=0$, y $S'=R'=W=1$. Cuando W (=1) está en $a$, tenemos $x=l$; $S=R=1$, y $S'=R'=0$. Trácese $a'a''$ y $b'b''$, cada una = W (=1), y júntense $a''b'$ y $a'b''$. Luego, con W en $c$, el esfuerzo cortante (positivo), S, en cada punto, como $f$, entre $c$ y $a$, está dado por la ordenada, $c'g$, á la línea $a''b'$; mientras la ordenada, $c'h$, á la línea $a'b''$; da el esfuerzo (negativo) en cada punto, como $e$, entre $c$ y $b$.

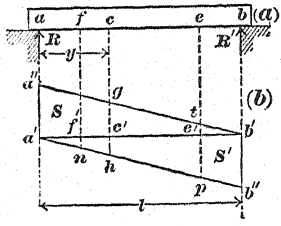

**Fig. 156.**

**352.** De modo semejante, con W en $e$, la ordenada, $e't$, da el esf cort (positivo) en cada punto, como $c$, entre $e$ y $a$; mientras que $e'p$ da el (negativo) en cada punto entre $e$ y $b$.

**353.** Se notará que, á medida que el peso, W, pasa de un lado al otro de cualquier punto, como $c$, el esf cort en este punto se invierte, siendo el cambio total del esf cort $= a'a'' + c'g = hg =$ al peso, W.

**354.** Con un peso, W (=1), en $b$, el esf cort en $c$, es = 0. Véase § 351. A medida que el peso avanza de $b$ hacia $a$, el esf cort positivo, $S = R = \frac{x}{l}$, en $c$, crece en proporción á las ordenadas á la línea $b'g$, haciéndose $= c'g = \frac{l-y}{l}$, cuando W esté justamente á la derecha de $c$. Con W justamente á la izquierda de $c$, tenemos el esf cort negativo en $c = S' = R' = c'h = \frac{y}{l}$. Pero, á medida que W avanza de $c$ hacia $a$ este esf cort negativo, en $c$, decrece en proporción á las ordenadas á la línea $ha'$, haciéndose 0 cuando W llega á $a$. Así, $a'hgb'$ es el diagrama de influencia del esf cort para el punto, $c$. Del mismo modo $a'ptb'$ es el del punto $e$, etc.

---

*N. del T.* — Así dice el texto inglés, pero R' y S' *no* varían en razón inversa de $x$, pues $x$ es sólo sustraendo en el numerador. Es cierto que disminuyen aumentando $x$, y, á la inversa, aumentan cuando $x$ disminuye, pero no *en razón inversa*.

**355.** Si una serie de pesos concentrados casi uniformes y equidistantes, tales como los pesos de ruedas de una locomotora y de un tren, entran en la luz por el apoyo *b* y avanzan hacia *a*, el esf cort en *c* aumenta evidentemente hasta que el primer peso llega al punto *c*. Disminúyese luego de repente en una cantidad = al primer peso á medida que ese peso pasa de *c*. Continúa luego disminuyendo, á medida que cada rueda pasa sobre *c*, pero más lentamente, hasta que el primer peso llegue al punto *a*. Véase § 358.

**356.** Con un peso *uniformemente distribuído*, igual á la unidad, por unidad de longitud, moviéndose como en el § 355, los esf cort en *c* (véase § 346) están representados por las áreas de aquellas porciones del diagrama, *a'hgb'*, sucesivamente cubiertas por el peso, tomándose como negativas las porciones del diagrama por debajo de la línea cero, *x'b'*. Así, cuando el principio del peso llega á *e*, el esf cort positivo en *c* está dado por el área del triángulo *b'e't*. Cuando llega el principio del peso al punto *c*, el esf cort en *c* llega á su máximo y está dado por el área del triángulo, *b'c'g*. Cuando el principio del peso llega al punto *f*, el esf cort en *c* es = área *b'c'g* — área *f'c'hn*.

**357.** De modo semejante, los esf cort en *e* están dados por las áreas de las porciones del diagrama, *a'ptb'*.

**358.** La fig. 157 * muestra el diagrama de influencia, 0 *dz* 14 16 para los esf cort en el punto 6, para un peso dado distribuído uniformemente, y tan largo

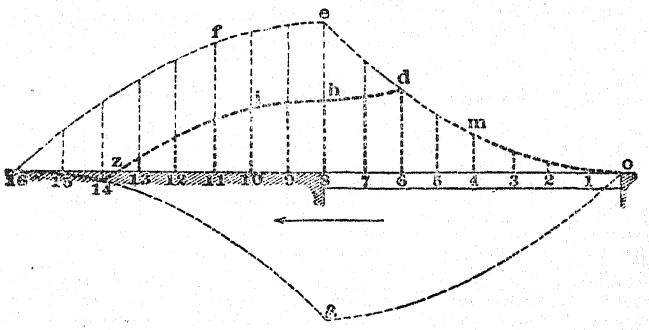

**Fig. 157.**

á lo menos como la abertura, llegando á ella en el punto 0, pasando al través y dejándola en el punto 8; también el correspondiente diagrama, 0, *e*, 16, para el apoyo izquierdo, 8; y el 0, *g*, 16 para el apoyo derecho, 0.

Para la acción de las resistencias internas en vigas y armaduras, véase « Resistencia transversal » en el capítulo « Resistencia de Materiales », y « Esfuerzos » en « Armaduras ».

## Relación entre el momento y el esfuerzo cortante.

**359.** El esf cort, en cualquier punto de la luz ó abertura, es simplemente la proporción en que va cambiando el momento de flexión en ese punto.

**360.** Así, en la fig. 158, el momento M, fig. (*b*), en el apoyo, *b*, debido al peso concentrado, W, de 6 lbs **, es = Wl = 6 × 4 = 24 p-lbs; pero, entre el apoyo y el peso, el momento va decreciendo en la proporción *uniforme* de 6 p-libs por cada pie de *x*, ó 6 pies-lbs por pie = 6 lbs; y estas 6 lbs son el esfuerzo cortante uniforme, V, fig. (*c*), en toda la viga. En consecuencia, el diagrama del esf cort, fig. (*c*), es una línea *horizontal;* esto es : sus ordenadas son de *igual* longitud.

**361.** Otra vez, en la fig. 159, las ordenadas del diagrama del esf cort entre *a"* y *o"*, fig. (*c*), son *positivas*, y demuestran el *aumento* (algebraico) del momento de flexión, M, fig. (*b*), á medida que pasamos del apoyo izquierdo, *a*, hacia el centro, *o*, de la luz; mientras que, las ordenadas negativas del diagrama del

* Por primera vez publicada en nuestra 9.ª edición de 1885.
** Véase *N. del T.*, pág. 462.

esfuerzo cortante, entre $o''$ y $b''$, muestran la disminución (algebraica) del momento de flexión, á medida que pasamos del centro, $o$, hacia el apoyo derecho, $b$. En el centro, $o$, la proporción del cambio del momento de flexión es cero, como lo es también el esf cort vertical.

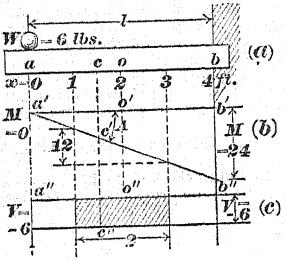

Fig. 158.

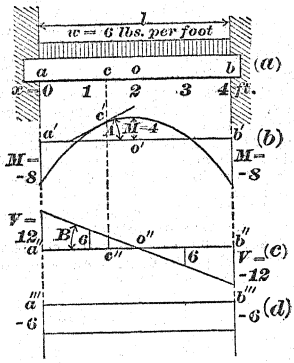

Fig. 159.

**362**. Tanto en la fig. 158 como en la 159, el momento de flexión, M, cambia constantemente; pero en la fig. 158 su *tipo de cambio* (=6 p-libs por pie de luz) es *constante**. En consecuencia, el diagrama del *momento* es una línea *recta inclinada*, y el diagrama del esfuerzo cortante es una línea *horizontal;* mientras que en la fig. 159 el tipo de cambio del momento de flexión está variando constantemente, siendo =12 p-lbs por pie de luz (el esfuerzo cortante=12 lbs) en el apoyo, y disminuyendo hasta cero en el centro, $o$. En consecuencia, en la fig. 159, el diagrama del momento, fig. ($b$), no es ya recto, sino *curvo;* y el diagrama del esf cort, fig. ($c$), no es ya horizontal, sino *inclinado*.

**363**. Pero, en la fig. 159 ($c$), el esfuerzo cortante, V, ó el *tipo* de cambio del momento de flexión (aunque no ya *constante*, como lo era en la fig. 158 ($c$), sin embargo *disminuye uniformemente*, á medida que pasamos de $a$ hacia $b$. Así, en el punto, 1, fig. 159, en el medio entre $a$ y $o$, el momento de flexión está cambiando al tipo de 6 p-lbs por pie, ó á la mitad de la proporción que tenía en $a$. Así, el diagrama del esfuerzo cort, aunque no es ya una línea *horizontal*, es todavía una línea *recta;* y la disminución *uniforme* (=6 p-lbs por pie por pie) en el tipo de cambio del momento de flexión, ó la disminución *uniforme* (=6 lbs por pie) en el esf cort, está indicado por el diagrama *horizontal* en la fig. 159 ($d$).

**364**. En una ú otra fig. trácese una línea recta, tangencial al diagrama del momento ($b$), en cualquier punto, $c'$, y formando con la línea horizontal $a'b'$ que indica el cero, un ángulo, A. (En la fig. 158 esta línea coincide con el diagrama del momento.) Entonces, la tangente de A está dada por la ordenada del diagrama del esf cort, $c''$, correspondiente al punto $c$, ó, para cualquier punto, V=tang A.

**365**. En la fig. 158, donde este ángulo A, fig. ($b$), es *constante*, las ordenadas del esf cort, fig. ($c$), son de longitud *constante*. En otros términos, el diagrama del esf cort, fig. 158, es una línea *horizontal*.

**366**. Puesto que las ordenadas del diagrama del esf cort representan *fuerzas* (como lbs, kgs, etc.) y las abscisas representan *distancias* (como pies, metros, etc.), el producto de la distancia entre cualesquiera dos ordenadas del esfuerzo cortante multiplicada por el término medio de esas ordenadas, es un *área*, que representa un *momento* (en kgm ó p-lbs, etc.). Este momento es=á la diferencia entre los dos momentos representados por las correspondientes ordenadas en el diagrama de los momentos.

---

* Véase *N. del t.*, pág. 462.

**367.** Así, en la fig. 158 (*b*), el aumento en el momento (negativo) de la flexión entre los puntos 1 y 3, es=18 — 6=12 p-libs; y, en la fig. 158 (*c*), el momento representado por el área (sombreado), entre los mismos dos puntos, es=2 p×6 lbs=12 p-lbs. En la fig. 159, el aumento (algebraico) del momento de flexión, fig. (*b*), entre el apoyo izquierdo, *a*, y el centro, *o*, de la luz, es=8+4=12 p-lbs; y el momento, representado por el área (triángulo) del diagrama del esf cort, entre los mismos dos puntos, fig. (*c*), es

$$= \frac{1}{2} \text{V} \frac{l}{2} = \frac{12 \times 2}{2} = 12 \text{ p-lbs.}$$

**368.** Otra vez, en la fig. 159, en cualesquiera dos puntos igualmente distantes del centro, *o*, de la abertura, los momentos son iguales; ó la diferencia de los momentos=cero; y, puesto que las ordenadas del esf cort por debajo de la línea de cero, $a''b''$, fig. (*c*), se consideran como *negativas*, la suma algebraica de los dos triángulos del esfuerzo cortante correspondientes, fig. (*c*), es también=cero.

De modo semejante, las áreas en la fig. 159 (*d*) corresponden á las diferencias de ordenadas en la fig. 159 (*c*).

## Diagrama para reacciones, esfuerzos cortantes y momentos.

**369.** En la fig. 58 (*b*), p. 403, *cw* y *w*X dan respectivamente las reacciones de los apoyos derecho é izquierdo, *w* y *x*, fig. 58 (*a*).

**El esfuerzo cortante**, §§ 325, etc., es constante para todas las secciones entre cualesquiera dos pesos. Para el esf cort en cualquiera sección así situada, como *d*, encuéntrense, en el polígono de equilibrio, fig. 58 (*b*), las líneas, *cw* y *bc*, que representan las fuerzas, *w* y *c*, á la derecha, ó las *w*X, X*a*, *ab*, que representan las fuerzas *x*, *a*, *b*, á la izquierda, de la sección. Entonces la línea, *bw*, = *cw* — *bc*, ó *wb*=*w*X — X*a* — *ab*, representa la resultante de uno ú otro juego de fuerzas, y así representa el esfuerzo cortante en la sección, *d*.

**Para encontrar el momento de flexión** en cualquier sección, como *d*, fig. 58 (*a*); desde *d* trácese una vertical, cortando las líneas *sr* y *np* del polígono de las cuerdas, y sea *y*=al largo de la ordenada, comprendida, entre aquellas dos líneas.

Prolónguense *sr* y *np* de modo que se corten en *e*. Entonces *e* es el punto de aplicación de la resultante, U=*bw*, fig. 58 (*b*), de las dos fuerzas á la derecha de *d*, á saber: del peso *c* representado en la fig. 58 (*b*) por *bc*, y la reacción en *w*, representada por *cw;* porque si el peso, *c*, y la reacción en *w* se movieran, necesitaríamos, para el equilibrio, una reacción vertical, *bw*=*cw* — *bc;* y las líneas correspondientes, *b*O y *w*O, en el diagrama de fuerzas, son respectivamente paralelas á *np* y *sr* en el polígono de cuerda.

En otros términos, eliminando el peso, *c*, y la reacción en *w*, y sustituyendo la resultante de ellos, U=*bw*, sustituímos también un nuevo polígono *smnes*, fig. 58 (*a*), con U (=*bw*) aplicado en *e*.

En la sección *d*, sea L el brazo de palanca de esta resultante, U,=la distancia horizontal desde *e* hasta *y*. En la fig. 58 (*b*), trácese O*h* horizontal, representando la componente horizontal de cada una de las fuerzas XO, *a*O, etc. Sea H=á la longitud de O*h*. Entonces el momento de flexión, en la sección *d*, es M=H*y;* pues M=UL; y, por los triángulos semejantes, L : *y*=H : U; ó UL=H*y*.

**Escala de los momentos.** Puesto que M=H*y*, podemos, escogiendo la posición de O * á distancia conveniente de X*c*, obtener la escala de momentos que se quiera para medir los momentos directamente, sobre *y*. Así, supongamos que se ha usado una escala de 1 pulgada=2 pies en la fig. 58 (*a*), y que se desea tener una escala para los momentos de 1 pulgada=50 p-lbs. Entonces necesitamos solamente escoger de tal manera la posición de O *, que su distancia, H, de X*c*, represente 50 p-lbs ÷ 2 pies=25 lbs, en la escala de la fig. 58 (*b*). Entonces 1 pulgada de longitud de *y* corresponderá á 2 p×25 lbs=50 p-lbs †.

---

* Véase § 95, pág. 397.

† *N. del T.* — No hemos creído necesario cambiar el sistema de medidas inglesas en estos §§, pues aquí es tan claro como el métrico para la exposición de la teoría.

# RESISTENCIA DE MATERIALES

## PRINCIPIOS GENERALES

**1.** Las fuerzas que obran sobre un cuerpo, pueden hacerlo de tal manera, que sus partículas tiendan á moverse simultáneamente, con diferentes velocidades ó en diferentes direcciones; para hacer esto, las partículas deben cambiar sus posiciones relativas. Esto ocurre, por ejemplo, cuando un cuerpo está situado de tal modo que se opone al movimiento relativo de otros dos cuerpos; como cuando un bloque está situado entre un peso y una mesa horizontal. Aquí los dos cuerpos (peso y mesa) tienden á juntarse; pero no lo pueden hacer sin deformación del cuerpo, y éste resiste á la deformación con *fuerzas internas* que obran entre las partículas del bloque y tienden á mantenerlas en sus posiciones relativas originales. La acción de estas fuerzas internas se llama *resistencia* del cuerpo ó de la materia que lo forma.

**2.** De modo análogo, si un cuerpo está suspendido por una cuerda larga y se le empuja ó se tira de él hacia un lado, las partículas sobre las que obra la fuerza tienden á moverse primero y la transmisión de esta tendencia, á las otras partículas, produce resistencia dentro del cuerpo.

**3.** Para el equilibrio interior, **las resistencias internas deben equilibrar las fuerzas externas.** Por eso se acostumbra á veces, llamar « esfuerzo » á cualquiera de las dos.

**4.** Supongamos las dos fuerzas *a* y *b*, figs. A, B, obrando sobre el cuerpo, *o*, bajo un ángulo *aob*. Las dos componentes, iguales y contrarias, *a"o*, y *b"o*, producen compresión ó tensión en el cuerpo, *o*, como en el § 1; en tanto que las otras dos componentes, *a'o* y *b'o*, se unen para formar la resultante *co* que, si no está equilibrada por otras fuerzas, moverá el cuerpo, *o*, en su propia dirección, produciendo, como dice el § 2, otra compresión, fig. A, ó tensión, fig. B.

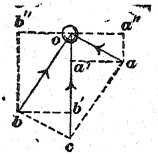

**Fig. A.**

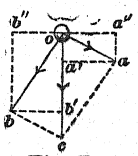

**Fig. B.**

**5. Sobre cualquier plano,** dentro de un cuerpo, puede obrar una fuerza (**1**) **normal**, (**2**) **tangencial**, (**3**) ú **oblicua**. Si obra oblicuamente, se descompondrá en dos (véase Estática, § 65), una obrando normal, y la otra, tangencial al plano.

**6.** Considerando las dos porciones en que queda dividido el cuerpo, por dicho plano, las fuerzas (**1**) obrando normalmente al plano, producen **tensión** (ó **compresión** en el plano, tendiendo á separar las dos porciones, ó á comprimirlas entre sí); y (**2**) las fuerzas que obran **tangencialmente** al plano, producen esfuerzo cortante (ó **torsión**) en el plano, tendiendo á hacer resbalar las dos porciones, una sobre la otra, en línea recta (ó con un movimiento de torsión). **La torsión** ocurre en planos paralelos y entre **dos pares contrarios**, como en las secciones transversales del eje ó árbol de un freno de mano al aplicarlo.

**7.** Así, si una barra de hierro es estirada (ó comprimida) en el sentido de su longitud, sus secciones transversales soportan tensiones (ó compresiones) normales. Si es cizallada transversalmente (ó torcida), las secciones transversales, entre, y paralelas á las dos fuerzas de cizallamiento ó de torsión, resisten á ellas; es decir, al esfuerzo cortante.

**8.** En cualquier punto de la trayectoria circular de un esfuerzo de torsión, se pueden considerar las tangentes á la trayectoria, como representando esfuerzos cortantes. **La torsión** es por consiguiente un simple esf cort que cambia de dirección en cada punto.

**9. Esfuerzo transversal.** En la fig. 124, pág. 459, las dos fuerzas, iguales y paralelas, W y R, en opuestas direcciones, producen un esfuerzo tangencial = W = R, en el plano vertical entre sus líneas de acción; pero W y R como un *par*, tienen un *momento*, que debe, para el equilibrio, ser destruído por el momento igual de otro par, como C y T; y la oposición de estos dos pares produce esfuerzos normales (compresión y tensión) en los mismos planos verticales entre W y R y paralelo á ellas.

**10.** La mayor tendencia de la acción de fuerzas, exteriores y opuestas, es romper el cuerpo, separando sus partículas. Aun bajo compresión, la ruptura ocurre sólo por separación de partes.

## Alargamiento.

**11.** Cuando las resistencias interiores y las fuerzas exteriores están en equilibrio, no hay deformación; pero al empezar la acción opuesta de las fuerzas externas, cuando aún no se han desarrollado las resistencias interiores, comienzan las deformaciones bajo la acción de aquéllas, aún no equilibradas. (Véanse §§ 35, etc.) Pero las resistencias entran en acción por las deformaciones y crecen con ella; y si las fuerzas exteriores no pasan el límite de elasticidad (§ 26), las resistencias acaban por igualarla y evitan ulteriores deformaciones.

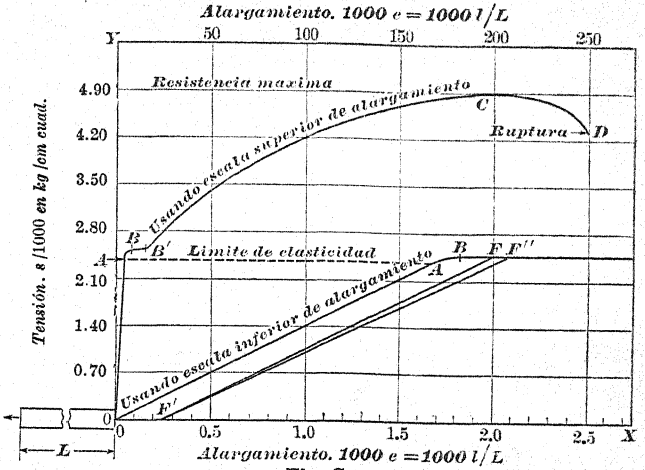

**Fig. C.**

## Conducta bajo una tracción normal.

**12.** La fig. C **demuestra cómo se conduce un material típico** (acero blando) **bajo tracción.** De 0 á A, es decir, bajo el límite de elasticidad (§ 26), digamos 34,000 lbs por pulg (=23.9 kg por milímetro cuad), el estiramiento crece, proporcionalmente á la tracción, como lo indica la línea recta, 0A. El comienzo del proceso, está representado en el diagrama *bajo* en que la escala de alargamientos es 100 veces mayor que la del diagrama superior. Después del punto A los alargamientos crecen más rápidamente que las tensiones; y, entre B y B', el alargamiento (en hierro y acero) crece, aumentando muy poco ó no aumentando la tensión; y, aunque ésta disminuya un poco *, B es el punto donde *cede* (**yield point**). Véase § 31. La escala del diagram abajo no pasa de B'. Más allá de B', (diagrama superior) el alargamiento aumenta mucho menos rápidamente que

* Véanse §§ 16 y 17.

entre B y B', y es por algún tiempo proporcional á la tracción * (aunque mucho mayor, relativamente al alargamiento, que en 0A); pero ahora los alargamientos van cada vez más rápidamente aumentando en relación con la tracción, hasta que ésta llegue á su **maximo** (digamos 70,000 lbs por pulg =49.2 kg por milímetro cuad) en C. Aquí, el alargamiento crece sin que crezca la tracción (línea horizontal); y más allá de C, el alargamiento continúa creciendo, aunque la tracción disminuya, hasta que finalmente en D viene la **ruptura.**

**13.** Si después de pasar el límite de elasticidad, se suspende el esfuerzo en la barra como en F, fig. C, diagrama bajo, la barra no vuelve á su primitiva longitud antes de sufrir la tracción. El alargamiento, 0F', con que queda, se llama **permanente.** La línea FF' es, en general, aproximadamente paralela á la línea 0A, de alargamientos proporcionales á la tensión. Cuando se vuelve á aplicar la misma tracción, el alargamiento es mayor que antes, en una pequeña cantidad, representada por la línea FF".

**14.** Cuando la tracción se hace **dentro del límite de elasticidad** (§ 26), la longitud recuperada al cesar la tensión, es tan próxima á la primitiva, que el alargamiento permanente no se puede indicar en la figura (§ 28).

**15.** Bajo la *tensión*, el **área de la sección** *disminuye*, y bajo la *compresión*, *aumenta*. En los materiales dúctiles, la reducción del área de la sección es muy notable, sobre todo en una parte relativamente pequeña de la longitud, generalmente cerca del medio, y la fractura ocurre normalmente en la sección más reducida.

**16.** En la fig. C, ambos diagramas, y en la fig. D, la curva continua, representan el **esfuerzo nominal por unidad de superficie**, ó sea el que se usa más. Este se encuentra dividiendo el esf total por el área *original* de la sección, como en el § 18.

**17.** Las curvas de puntos, fig. D, representan el esf **real por unidad de superf** encontrado, dividiendo el esf total por el *área verdadera de la sección*. Bajo *tensiones*, la tensión real por unidad es, por supuesto, *mayor*, y, bajo *compresiones*, la compresión real por unidad de superf es *menor* que las nominales correspondientes.

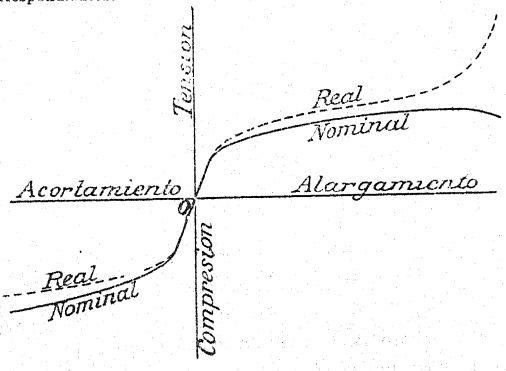

**Fig. D.**

**Coeficiente de elasticidad.**

**18.** Sea P=el **peso** (una de las dos fuerzas iguales y opuestas) que obra en uno de los extremos de la barra y en la prolongación de su eje; y sea $a$=al área de la sección transversal original de la barra. (Véanse §§ 16 y 17.) Entonces, $s = P/a$ es la tensión normal **por unidad de área** en la barra. Suponemos que, mientras las fuerzas obren en la dirección del eje de la barra, P está uniformemente distribuído sobre $a$, aunque esto sucede rara vez en la práctica.

**19.** Sea L=la longitud primitiva de la barra ó una porción determinada de ella, y $l$=el **alargamiento** * de la longitud L bajo la acción de una tensión, $s$, por

* Veanse §§ 16 y 17.

unidad de superficie. Entonces, $e=l/L$ es el alargamiento **por unidad de longitud** * correspondiente á la tensión, $s$, por unidad de superficie.

**20.** En muchos materiales, la tensión, $s$, por unidad de superficie, y el alargamiento, $e$, por unidad de longitud, crecen al principio proporcionalmente; y la relación $s/e$, ó la tensión por unidad de superficie ÷ por el alargamiento por unidad de longitud que es lo que se llama **coeficiente ó módulo de elasticidad** y se designa por E, permanece prácticamente constante; así

**Módulo ó coeficiente de elasticidad** = $E=s/e$ = tensión por unidad de sup ÷ alargamiento por unidad de long.

**20 a.** El módulo de elasticidad es así **proporcional á la tangente** del ángulo XOA, fig. C. La proporción depende de las escalas adoptadas.

**20 b.** El módulo de elasticidad, E, crece con la tensión por unidad de superficie requerida para producir una unidad dada de alargamiento. Por tanto, E es la medida de la *rigidez* del cuerpo, es decir, de su capacidad para resistir al cambio de forma. Por tanto, mejor le quedaría á este módulo el nombre de **módulo de rigidez.**

**20 c.** Si iguales tensiones adicionales pueden indefinidamente continuar produciendo iguales y adicionales alargamientos en una barra, suponiendo que no se pasa el límite de elasticidad, entonces una fuerza igual al módulo de elasticidad, aplicada como *tensión*, **doblaría el largo de la barra**, y como *compresión*, reduciría á *cero* su longitud.

**20 d.** Por ejemplo, dentro del límite de elasticidad, una barra de acero laminado de 6.25 cm cuad (1 pulg cuad) de sección se alargará ó acortará, término medio $\frac{1}{30{,}000}$ de su longitud por cada carga de 75 kg por cm cuad. Si ella se pudiera alargar ó acortar indefinidamente, en la proporción de $\frac{1}{30{,}000}$ de su longitud por cada 75 kg de peso adicional (siempre por cm cuad), entonces con 30,000 veces 75 kg, ó sean 2,250,000 kg (por cm cuad, que es más ó menos el módulo de elasticidad de tales barras), se podría ó alargar la barra al doble de su longitud ó reducir ésta á cero; según se la aplique.

**20 e.** Si fuerzas iguales é infinitesimales, aplicadas á una barra, producen siempre una relación constante en los cambios de longitud de la barra, alargamientos, si por *tensión* y acortamientos, si por *compresión;* entonces el mismo peso que *doblaría* la longitud original de la barra, aplicado como *tensión*, reduciría á la *mitad* su longitud original, aplicada como *compresión.*

---

* Consideramos á los *acortamientos*, bajo compresión, como **alargamientos negativos.**

**21. En una barra prismática, sometida á tensión longitudinal ó compresión,** sea

$W$ = peso total;
$a$ = área de la sección transversal;
$s = \frac{W}{a}$ = esfuerzo por unidad de superficie;
$L$ = longitud original;
$l$ = alargamiento * total;
$e = l/L$ = alargamiento * por unidad de longitud original;
$E$ = módulo de elasticidad de la substancia;
$r = Ea$ = una medida de la resistencia de la barra.

Entonces

**Módulo de elasticidad** $= E = \frac{W}{a} \cdot \frac{L}{l} = s/e$ ..... (1)

**Carga total** $= W = Ea \cdot \frac{l}{L} = re$ ..... (2)

**Esfuerzo por unid de super** $= s = \frac{W}{a} = Ee$ ..... (3)

**Alargamiento total** * $= l = \frac{W}{a} \cdot \frac{L}{E}$ ..... (4)

$= s \cdot \frac{L}{E}$ ..... (5)

**Alarg. por unidad de long** * $= e = \frac{l}{L} = \frac{W}{aE} = \frac{s}{E}$ ..... (6)

**22. En una viga,** apoyada en ambos extremos y cargada en el centro, sea

$L$ = longitud de la viga en la luz ó abertura;
$w$ = peso — — —
$\Delta$ = flexión — — —
$b$ = ancho de la sección transversal de la viga;
$d$ = profundidad — — —
$I$ = momento de inercia — —

Entonces

$$E = \frac{(W + \frac{5}{8} w)\, L^3}{48\, \Delta\, I} \quad \ldots\ldots (7$$

Si la viga es rectangular, $I = \frac{bd^3}{12}$ (véase Momentos de inercia, pág. 491) y

$$E = \frac{12\,(W + \frac{5}{8} w)\, L^3}{48\, \Delta\, bd^3} = \frac{(W + \frac{5}{8} w)\, L^3}{4\, \Delta\, bd^3} \quad \ldots\ldots (8)$$

**Para vigas** (véanse también págs. 502 y 503).

**23. El inverso del módulo de elasticidad. El módulo de elasticidad** $= \frac{\text{tensión por unid de sup}}{\text{unidad de alargamiento}}$, indica la tensión requerida para producir cierto alargamiento.

**Su inverso,** $= \frac{\text{unidad alarg}}{\text{tensión por unid de sup}}$, indica cuanto debe deformarse una barra, etc., de un material dado para producir cierto esfuerzo. Esto puede ser de mucha importancia, especialmente en las construcciones de madera, cuyo módulo de elasticidad es bajo, relativamente al del acero; y en las que puede presentarse una gran deformación relativa antes de que la resistencia de seguridad máxima de las fibras entre en acción. Así, en el caso de un muelle, por ej., sostenido por largos pilotes de madera, pueden éstos estar sometidos á fuerzas laterales tan intensas que, produciéndoles fuertes flexiones, den á la carga que resisten

* El *acortamiento* por la compresión lo consideramos como alargamiento negativo.

tan largos y peligrosos brazos de palanca, horizontales, que resulten grandes y peligrosos momentos capaces de volcar y destruir la obra.

**24. Módulo de elasticidad variable.** Los experimentos sobre hormigones de cemento muestran un ejemplo (para ambos, tensión y compresión) de un material, en el cual el módulo de elasticidad, E, cambia constantemente; los alargamientos crecen más ligero que las tensiones.

**25.** Sin embargo, en el caso de materiales dúctiles, los alargamientos producidos por tensiones, dentro del límite de elasticidad (§ 26), son tan pequeños y tan irregulares, que no se puede llegar á un valor satisfactorio del término medio de dicho módulo sino comparando muchos experimentos. En el caso de materiales quebradizos, donde apenas se nota una insignificante deformación antes de la ruptura, es muy incierta la determinación de este módulo.

## Límite de elasticidad.

**26.** La tensión OA, fig. C, más allá de la cual los alargamientos de cualquier cuerpo crecen perceptiblemente con más rapidez que las tensiones, se llama el **límite de elasticidad.** Debido á la irregularidad en la conducta de diversas muestras de un mismo material y la extrema pequeñez de las deformaciones causadas en la mayor parte de los materiales por pesos moderados, y porque no podemos muchas veces saber en qué momento los alargamientos empiezan á crecer más rápidamente que las cargas, resulta que rara vez se puede determinar con exactitud el límite de elasticidad *. Pero, por medio de un gran número de experimentos sobre un material dado, se puede obtener un valor medio ó mínimo, muy útil para mantener en todos los casos prácticos las resistencias dentro de tales valores; puesto que, si se pasa del límite de elasticidad (por errores de cálculo ó debido á aumento de las fuerzas contra el material ó á disminución en la resistencia de éste), la construcción se derrumbará rápidamente. La tabla del § 30 da los términos medios aproximados de los límites de elasticidad de algunos materiales. El límite de elasticidad, como lo hemos explicado aquí, se llama algunas veces **el verdadero límite de elasticidad.**

**27.** Los materiales quebradizos, como piedras, cementos, ladrillos, etc., apenas puede decirse que tienen un límite de elasticidad, ó si lo tienen es casi imposible determinarlo, ya que la ruptura se efectúa en tales cuerpos antes que se pueda medir satisfactoriamente ninguna deformación.

**28.** Probablemente, siempre queda un pequeño alargamiento **permanente,** aun bajo pesos moderados; pero generalmente viene á hacerse perceptible, más ó menos, en el momento en que se pasa del límite de elasticidad. **El límite de elasticidad se define algunas veces** como la tensión bajo la cual se observa el primer alargamiento permanente.

**29. El cociente elástico** de un material es el cociente, $\frac{\text{límite de elasticidad}}{\text{la máxima resistencia}}$

Se expresa generalmente por una fracción decimal.

La carga de trabajo permitida para un material debe determinarse más bien por su límite de elasticidad que por su resistencia máxima. En igualdad de condiciones, un elevado cociente máximo de elasticidad es en general cualidad deseable; pero, por otra parte, es posible, modificando los procedimientos de manufactura, obtener materiales de elevados cocientes de elasticidad, pero de poca rigidez, es decir, de poca capacidad para resistir golpes ó choques, ó aplicaciones repentinas, ó fluctuaciones bruscas de fuerzas. Véanse §§ 34, 35, etc.

En la manufactura del acero, el cociente elástico se aumenta, aumentando la reducción del área en el martilleo ó la laminación, y la proporción del aumento del cociente elástico con las reducciones de áreas, aumenta rápidamente á medida que se hace muy grande la reducción. Kirkaldy encontró **

**31. Punto cedente** (*Yield point*) §. **Límite elástico, comercial, relativo ó aparente.** Al probar muestras de hierro y acero encuéntrase comúnmente que, en un esfuerzo que excede ligeramente del verdadero límite elástico (§ 26), el alargamiento empieza á crecer *sin más aumento de peso*. Este punto se llama de ordinario « el punto cedente » ó « el límite de elasticidad » en las pruebas comerciales. La Comisión francesa de métodos de probar los materiales de construcción lo llamó « el límite de elasticidad aparente ». El finado profesor J. B. Johnson (« Los Materiales de Construcción », Nueva York, John Wiley and Sons, 1906, pág. 19), aplicó el término « límite elástico relativo ó aparente » á aquel punto en el diagrama de la fuerza en que la proporción de deformación es 50 por ciento mayor que en puntos que estén por debajo del verdadero límite de elasticidad.

* En el hierro laminado y el acero, el módulo de elasticidad es notablemente constante. En el hierro forjado, el límite de elasticidad depende principalmente del grado de reducción de la sección transversal, en el laminado; teniendo los tamaños más pequeños el límite más alto. En el acero este efecto es menos marcado.

** Véanse §§ 25, 26.

*** En la madera, « la fuerza de la fibra extrema en el verdadero límite de elasticidad (§ 26) de una viga es prácticamente idéntica á la fuerza compresiva perpendicular del material ». Véase cuadro del art. 1, **Resistencia á la compresión** de las maderas americanas, en Resistencia de las maderas, después de Explosivos modernos.

§ *N. del T.* — Este punto lo llaman los americanos « Yield point », y como hemos consultado muchos diccionarios y varios ingenieros notables sin encontrar como se expresa con brevedad su significado, hemos resuelto llamarlo « Punto cedente », porque es precisamente el punto en que la barra sigue alargándose *sin que se aumente el esfuerzo á que está sometida*, y puede considerarse como el tercer período elástico Marvá, Mecánica aplicada); caracterizado además porque el alargamiento se localiza y se « forma el huso » ó región de la gran contracción transversal ó *estrechamiento de sección*.

## Resistencia viva.

**32. La resistencia viva** de una barra, bajo un esfuerzo $s$, es el trabajo hecho sobre la barra, al producir esa fuerza, ó teóricamente, el trabajo que hará la barra, al recobrar su forma original, cuando deja de obrar el esfuerzo. Ordinariamente nos referimos á la **resistencia viva elástica**, ó sea la que corresponde al esfuerzo $s_e$ en el límite de elasticidad.

**33.** Sea

$s_e$ = al esfuerzo por unidad de superficie en el límite de elasticidad;

$a$ = área de la sección de la barra;

$P_e = as_e$ = la carga ó peso correspondiente á la tensión $s_e$;

L = al largo original de la barra;

$l$ = á su alargamiento, en el límite de elasticidad;

E = al coeficiente ó módulo de elasticidad.

El trabajo se ha hecho por la carga *media* $P_e/2 = as_e/2$, obrando en la distancia $l = L\, s_e/E$. En consecuencia:

$$\textbf{Resistencia viva} = K = P_e l/2 = as_e L s_e/2E = (s_e^2/2E)aL.$$

**34.** Aquí $s_e^2/2E$ es el **módulo de resistencia viva** = á la resist viva de una barra que tiene la unidad de área por sección y la unidad de longitud (Hágase en la fórmula, $a = 1$, $L = 1$.)

El módulo de resistencia viva de un material da la medida de su capacidad para resistir choques ó golpes.

## Pesos aplicados repentinamente.

**35.** Suspéndase un cuerpo, de peso, W, por una cuerda, y dispóngase de modo que no haga sino tocar el platillo de una balanza de resorte sin hacerlo bajar. Córtese entonces la cuerda con unas tijeras.

**36.** En el momento de cortar la cuerda, el resorte no se ha estirado; su esfuerzo resistente, S, es por tanto cero, y la fuerza de descenso neta ó resultante, que obra sobre el cuerpo, es $F = W - S = W - 0 = W$.

**37.** Bajo la acción de esta fuerza, el resorte se estira, y S aumenta proporcionalmente con el estiramiento. En consecuencia (quedando constante W) la fuerza del descenso, aceleratriz, F, que obra sobre el cuerpo, disminuye hasta que $S = W$, entonces $F = W - S = W - W = 0$.

**38.** El cuerpo, hasta entonces constantemente acelerado (por una fuerza decreciente, F), ha aumentado constantemente su velocidad. Sea $h$ = á la altura de donde ha caído ahora, y sea $x$ el punto alcanzado, al extremo de $h$.

**39.** Más allá de $x$ (quedando constante W, mientras S continúa aumentando), obra sobre el cuerpo una fuerza ascendente retardatriz constantemente creciente, $-F = W - S$, que lo lleva al reposo en un segundo punto, $z$, al fin de una segunda distancia = $h$. Su **caída total** es por tanto. = $2h$.

**40.** Sea S máx = al valor máximo de S, ó el que tiene al término $z$, de la caída, $2h$. Entonces, puesto que S ha aumentado proporcionalmente con $h$, su valor *medio* durante la caída, $2h$, fué S máx/2; y el trabajo hecho, durante la caída entera, $2h$, fué $2Wh = (S\ máx/2)\ 2h = S\ máx \times h$. En consecuencia,

## S máx = 2 W.

**41.** Al término, $z$, de la caída, $2h$, el cuerpo, al llegar al reposo, es movido por una fuerza ascendente, $-F = W - S$ máx $= W - 2W = -W$; y (despreciando la fricción) se repite ahora el mismo fenómeno, pero en dirección ascendente, y así indefinidamente.

**42. Pero las pérdidas de energía**, debidas á la resistencia del aire y á la fricción interna, hacen cada oscilación menor que su valor teórico; y el cuerpo en definitiva va á reposar en el punto, $x$, á mitad de la distancia de la caída $2h$.

**43.** Así (§ 40) dentro del límite de elasticidad, **un peso, aplicado de súbito** (aunque sin choque), **produce temporalmente un alargamiento** casi igual **á dos veces el que pudiera producir aplicado gradualmente**; esto es: dos veces el que puede sostener después de quedar en reposo; y desarrolla temporalmente, en el cuerpo alargado, **una resistencia = dos veces el peso.**

**44. Si el peso se agrega en pequeñas porciones**, cada una aplicada repentinamente, entonces cada porción produce un pequeño alargamiento temporal que después se reduce y queda con un valor mitad. Bajo la última pequeña porción

de peso, el resorte se estira temporalmente hasta una longitud mayor que la que puede mantener el peso total, por un valor igual á la mitad del pequeño estiramiento temporal producido por la aplicación súbita de la última pequeña porción de peso.

**Una sección puede debilitarse aumentando el ancho.** En las páginas 418, etc., consideramos el caso en que el ancho de la base era fijo y en que el punto de aplicación de la resultante de las fuerzas que obraban sobre ella cambiaba de posición en dicha base. Mencionaremos ahora el caso en que la resultante se aplica á una distancia constante de un extremo de la base, pero en que esta base es de ánch variable, de manera que la distancia constante pueda ser igual, mayor ó menor que la mitad de ella.

La fig. E representa una vista de lado de una barra de espesor uniforme = 1*, pero (como se indica) de ancho variable y sometida á presiones, cuya resultante P es = 1* y pasa por el centro de la sección *ab* de ancho igual á 1 * **.

Fig. E.

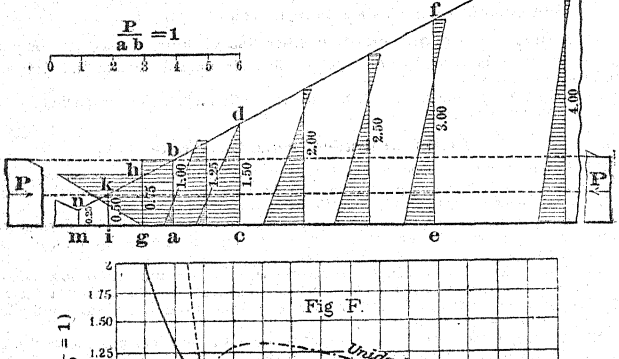

Fig F.

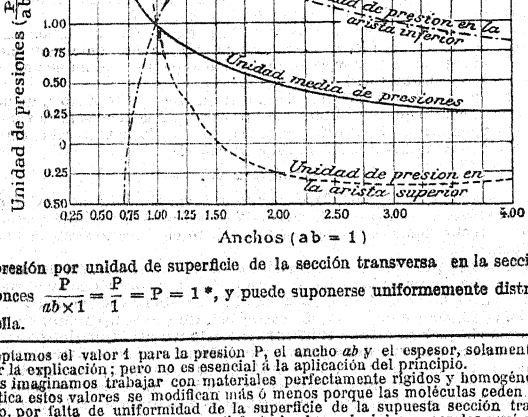

La presión por unidad de superficie de la sección transversa en la sección *ab*, es entonces $\frac{P}{ab \times 1} = \frac{P}{1} = P = 1$ *, y puede suponerse uniformemente distribuída sobre ella.

* Adoptamos el valor 1 para la presión P, el ancho *ab* y el espesor, solamente para facilitar la explicación; pero no es esencial á la aplicación del principio.

** Nos imaginamos trabajar con materiales perfectamente rígidos y homogéneos. En la práctica estos valores se modifican más ó menos porque las moléculas ceden bajo el esfuerzo, por falta de uniformidad de la superficie de la supuesta sección transversal, etc. Sin embargo, son bastante satisfactorios los principios generales aquí establecidos.

Pero en otras secciones de la barra, la resultante se halla más cerca de una arista que de la otra, y la fuerza por unidad de superf no puede entonces suponerse por más tiempo uniformemente distribuída sobre la sección transversal; pero, como se explicó en las págs. 418 á 422, dicho esfuerzo adquiere el valor máximo en la arista más próxima á la resultante, y disminuye gradual y uniformemente hasta llegar á un mínimo en la arista más distante.

Esto se indica por medio de triángulos sombreados, etc., en la fig. E, y por medio de curvas en la fig. F, que indican el esfuerzo ó presiones medias por unidad de superficie * de las diversas secciones de la fig. E, y los esfuerzos ó presiones por unidad de superficie ejercidos en las aristas superiores é inferiores, respectivamente, calculados por las reglas de las págs. 419 á 422.

En la tabla siguiente se dan también estas presiones.

**Presión por unidad de superficie en la fig. E;** tomándose la presión por unidad $\frac{P}{ab}$ en la sección *ab* igual á 1 **.

| Sección. | Ancho. | Presión por unidad de superficie de la sección transversal. | | |
|---|---|---|---|---|
| | | Medio. | En la arista inferior *me.* | En la arista superior *nf.* |
| | 4.00 | .25 | .8125 | — .3125 † |
| *ef* | 3.00 | $^1/_3$ | 1.00 | — $^1/_3$ |
| | 2.50 | .40 | 1.12 | — .32 |
| | 2.00 | .50 | 1.25 | — .25 |
| *cd* | 1.50 | $^2/_3$ | $1^1/_3$ | 0 |
| | 1.25 | .80 | 1.28 | .32 |
| *ab* | 1.00 | 1.00 | 1.00 | 1.00 |
| *gh* | .75 | $1^1/_3$ | 0 | $2^2/_3$ |
| *ik* ‡ | .50 | 2.00 | —4 † | 8.00 |
| *mn* ‡ | .25 | 4.00 | —32 † | 40.00 |

**Es de importancia observar** que para una fuerza dada P, y para anchos, menores que 3*ab*, la sección más fuerte de esta barra no es *la más ancha*, sino aquella (*ab*) en que la resultante P pasa por el centro de la sección. En otras palabras, **una barra puede debilitarse aumentando su sección transversal,** si este aumento es tal que obligue á la resultante de las presiones á pasar por cualquiera otra parte que no sea el centro de cualquiera sección transversal. Esto es enteramente independiente del *peso* de la porción añadida.

Entre las secciones más anchas que *ab*, la más débil es aquella (*cd*) cuyo ancho es $=1.5ab$. En esta sección la arista inferior ó más baja *me* tiene por presión ó esfuerzo máximo por unidad de superficie $\left(=1^1/_3 \times \frac{P}{ab}\right)$, mientras que en *d*, en la arista superior, no hay presión. Más allá de *cd* la arista superior *nf* está sometida á *tensión* † y la presión por unidad de superf á lo largo de *me* decrece haciéndose

* En el caso discutido en las págs. 418 á 422, la presión media $un = \frac{P}{uv}$, permanece constante en tanto que la superficie entera *uv* entraba en juego. Aquí, al contrario, el área de la sección varía. Por tanto, la presión media por unidad de superficie varía también, y en razón inversa del área.

** Véase la nota * de la página anterior.

† En la actual discusión, así como en la de las págs. 418 á 422, hemos supuesto casos de *compresión*; pero, el principio es el mismo cuando las fuerzas se aplican por *tensión*. En tales casos, sin embargo, los términos « presión » y « tensión » están invertidos.

‡ Los esfuerzos por unidad de superficie en las aristas de la sección *ik* son demasiado grandes para indicarlos convenientemente en cualquiera de las figuras; y los de la sección *mn* (como lo indica la tabla) exceden con mucho los límites de las figuras. La presión en *k* sería $\frac{P}{o} = \infty$ (infinita) si no fuera por las tensiones que se ejercen en la parte inferior de la sección.

de nuevo $= \frac{P}{ab}$ en *ej*, en que el ancho *ej* es $=3ab$; y decreciendo aún más con ulteriores incrementos del ancho. Cuando el ancho se hace *menor* que *ab*, como en *gh*, etc., la arista *superior* de la barra se acerca más á la resultante que la arista inferior, y por tanto recibe la presión máxima.

Cuando el ancho es $=\frac{3}{4}ab$ como en *gh*, la distancia de la resultante á la arista superior es $\frac{1}{3}$ del ancho de la sección. La presión en la arista inferior es entonces $=0$; la presión media en *gh* es $\frac{P}{ab} \times \frac{1}{.75} = 1\frac{1}{3} \times \frac{P}{ab}$, y la presión en la arista superior es el doble de la presión media que se ejerce en *gh*, ó $2\frac{2}{3} \times \frac{P}{ab}$.

Cuando el ancho se hace menor que $\frac{3}{4}\ ab$, como en *ik* y *mn*, la presión en la arista inferior *mn* se hace negativa, es decir, se convierte en tensión.

Así, cuando como en *ik*, el ancho es $=\frac{1}{2}ab$, y la resultante pasa por la arista superior, la presión por unidad de superficie en esta arista es $=8 \times \frac{P}{ab}$, mientras que la arista inferior soporta una *tensión* de $4 \times \frac{P}{ab}$; y, á medida que la sección sea posteriormente reducida, estas fuerzas aumentan más y más, muy rápidamente. La condición de las secciones (tal como *mn*) en que la resultante pasa por fuera de ellas, es semejante á la de la sección *mn* de un gancho que sostenga un peso, como en la fig. G.

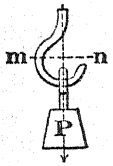

**Fig. G.**

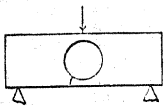

**Fig. H.**

La casa de William Sellers and Co., de Filadelfia, tuvo ocasión de ensayar un número de vigas de hierro fundido, provista cada una de una gran abertura circular como en la figura anexa. Estas vigas se rompieron, no por la sección más pequeña situada directamente debajo del centro de la abertura, sino un poquito hacia un lado, en donde la sección era más ancha, como se indica en la fig. H.

**Fatiga del material.** En los artículos siguientes sobre resistencia de materiales, la carga máxima ó carga de ruptura es aquella que, en su primera aplicación ó al obrar por primera vez, produce en un *corto* tiempo la ruptura de una pieza dada. Pero los experimentos de Wohler y Spangenberg muestran que una pieza puede quebrarse **aplicando sucesivamente** una carga mucho *menor* que aquélla y que mientras más á menudo se aplique la carga tanto menos se necesita para producir la ruptura. De este modo, el hierro forjado, que requiere una tensión de 3,726 kg por cm cuad para romperse después de obrar sobre él 800 veces, lo rompió una carga de 2,460 kg por cm cuad aplicada como 10 millones de veces sucesivas. El esfuerzo vuelve á cero después de cada aplicación en ambos casos.

**La diferencia** entre la tensión máxima y la tensión mínima de una pieza sometida solamente á tensión, ó entre la compresión máxima y la compresión mínima de una pieza sometida á compresión solamente, ó la suma de la tensión máxima y la compresión máxima de una pieza sometida alternativamente á ambos esfuerzos, la llamaremos **variación del esfuerzo** sobre la pieza. Cuando la dif de los esfuerzos extremos es menor que el límite de elasticidad, pueden repetirse las aplicaciones de la fuerza un número « enorme » de veces *.

* Esto no siempre es así en los casos en que el límite de elasticidad se ha aumentado artificialmente por medio de procedimientos de manufacturas, etc. Los esfuerzos á menudo repetidos, de tensión y compresión alternativa, inferiores á dicho límite, reducen éste al límite natural. Una ligera grieta puede ocasionar la ruptura por la acción de un esfuerzo aplicado relativamente pocas veces, de una intensidad ó *diferencia de esfuerzos extremos* sólo un poco mayor ó aún menor que el límite de elasticidad. El reposo entre dos esfuerzos aumenta la resistencia de la pieza. En muchos casos los esfuerzos un poco más allá del límite de elasticidad, aun si se los aplica á menudo,

Cuando se aplica un peso ó carga un número dado de veces, á una pieza, el peso que se requiere para producir la ruptura es el menor cuando la **dif de los esfuerzos extremos** es muy grande. Si los esfuerzos aplicados son alternativamente de tensión y de compresión, la ruptura tiene efecto más prontamente que si lo fueran siempre de tensión ó siempre de compresión. Esto es, tiene efecto con menores *variaciones de esfuerzos extremos* aplicados un número dado de veces, ó con menor número de aplicaciones de una **dif de esfuerzos extremos dada**. Para una **diferencia de esfuerzos extremos** dada y número dado de veces que ha de aplicarse, la circunstancia más desfavorable es cuando la tensión y la compresión son iguales.

Todo lo que hemos dicho se toma generalmente en consideración en el cálculo de las piezas de las construcciones de importancia sometidas á cargas movibles. Por ejemplo, Mr. Jos. M. Wilson, ingeniero civil, miembro del Instituto de ingenieros civiles de Londres, miembro de la Sociedad americana de ing. civs., emplea las fórmulas siguientes para determinar el « esfuerzo permitido » en los puentes de hierro, en kg por cm cuad, para calcularle á cada pieza el área de sección transversal que le corresponde.

Para piezas sometidas á **una clase de esfuerzos solamente** (todos de compresión ó todos de tensión) (*Obs. del T.* — Hemos cambiado los coeficientes de las notas para aplicarlas á medidas métricas) :

$$\mathbf{a} = u\left(1 + \frac{\text{esfuerzo mín aplicado á la pieza}}{\text{esfuerzo máximo aplicado á la pieza}}\right).$$

Para una pieza sometida **alternativamente á la tensión y á la compresión**, búsquese la compresión máxima y la tensión máxima ejercida sobre la pieza. Llámese el **más pequeño** de estos dos máximos « máximo menor » y el otro máximo más grande « máximo mayor ». Luego tendremos :

$$\mathbf{a} = u\left(1 - \frac{\text{máximo menor}}{2\ \text{máximo mayor}}\right).$$

Para una pieza cuya **comp máxima** y **tensión máxima** sean iguales, esta fórmula se convierte en

$$\mathbf{a} = u\left(1 - \frac{1}{2}\right) = \frac{u}{2}*.$$

La a de arriba es el esfuerzo de **tensión** permitido sobre cualquier pieza. Pero, el esfuerzo de **compresión** permitido se encuentra por la « fórmula de Gordon »**. Gordon dedujo de las experiencias de Hodgkinson las fórmulas siguientes :

Para **columnas cilíndricas macizas**. Carga de fractura :

$$P_o = \frac{5630\ w}{1 + H \times .0025\left(\frac{l}{d}\right)^2}.$$

Para la carga de trabajo ordinario, se usa la misma fórmula poniendo en el numerador 940 en lugar de 5630.

Para las **columnas huecas** la carga de fractura es

$$P = \frac{5630\ w}{1 + H \times .00125\left(\frac{l}{d}\right)^2}.$$

y la carga de trabajo ordinario se obtiene cambiando sólo, como se hizo antes, el factor 5630 por 940.

---

elevan dicho límite y la resistencia, pero hacen la pieza quebradiza y por tanto más propensa á la ruptura por medio de choques, y además un pequeño aumento de esfuerzo posterior disminuye rápidamente ó puede destruir enteramente la elasticidad. Un esfuerzo de *tensión* superior al límite de elasticidad hace descender notablemente ó puede aun destruir la elasticidad *compresiva*, y viceversa. Si un esfuerzo de tensión, a alargar una pieza, reduce su área de resistencia, puede así reducir su resistencia *total* aun cuando la resistencia *por cm cuad* haya aumentado. B. Baker encontró que el acero duro se fatiga mucho más ligero bajo la acción de cargas ó pesos repetidos que el acero dulce ó el hierro.

* Para el hierro laminado en compresión, $u = 455$ kg/cm cuad; para el mismo en tensión, $u = 490$.

** *N. del T.*— El autor cita aquí la fórmula de Gordon que no está ni en la página ni en la materia aludidas, pues esta edición, alterando una de las anteriores en que se hace la cita, ya no la trae. Para llenar este vacío la hemos tomado, con permiso de Marvá, de su « Mecánica », tomo 2.º, pág. 64.

En todas:

$w$ = área sección transversal en cm cuad;
$d$ = { diám columna maciza / — exterior columna hueca } en cm;
$l$ = longitud de la columna en cm;
P y $P_0$ = cargas en kg.

El coeficiente H del segundo término del denominador tiene los valores siguientes en relación con la disposición de los extremos de la pieza comprendida:

Para las dos bases planas, H=1.
Una base plana y otra redondeada ó articulada, H=2.
Dos bases redondeadas ó articuladas, H=4.

Los experimentos demuestran que el material puede fallar ó ceder sometido á un **esfuerzo muy prolongado** de mucha menos intensidad que la producida por la carga máxima ó carga de ruptura.

## RESISTENCIA TRANSVERSAL

**1.** En Estática, §§ 285, etc., discutimos la acción de las fuerzas externas ó destructivas sobre los cantilevers, vigas y armaduras. Aquí discutimos la reacción de las fuerzas (esfuerzos) internas ó resistentes en cantilevers y vigas sólidos, á fin de determinar sus pesos. Véanse también, §§ 104, etc.

**2.** A menos que de otro modo se diga ó aparezca, suponemos que las fuerzas en todas partes del cantilever ó viga, están dentro del límite de elasticidad.

### Condiciones de equilibrio.

**3.** Para el equilibrio, las fuerzas internas y sus momentos deben contrarrestar las fuerzas externas y sus momentos. En otros términos, si el cantilever ó la viga se suponen cortados por una sección en cualquier punto, debemos tener

(1) Σ fuerzas verticales =0
(2) Σ fuerzas horizontales=0
(3) Σ momentos =0

O:

(1) Suma algebraica de los esfuerzos verticales internos=suma algebraica de las *fuerzas* verticales externas en uno ú otro lado de la sección;

(2) Suma algebraica de las tensiones horizontales resistentes=suma de las *compresiones horizontales;* y

(3) Suma algebraica de los momentos de las *resistencias* internas=suma algebraica de los momentos de las *fuerzas* externas en uno ú otro lado de la sección.

**4.** Los cantilevers y las vigas de sección transversal uniforme tienen ordinariamente una superabundancia de resistencia contra el esfuerzo cortante. De aquí que la discusión de su resistencia verse principalmente sobre el equilibrio de los *momentos.* Para su resistencia al esfuerzo cortante vertical, véase Estática, §§ 325, etc., y pág. 528. Véase también Esfuerzo cortante horizontal, §§ 51½á 53, más abajo.

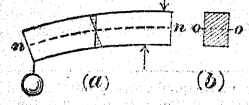

Fig. 1.

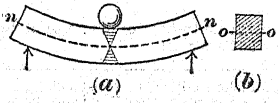

Fig. 2.

**5.** Para que haya equilibrio, el momento resistente, R (=la suma de los momentos resistentes, $r$, de todas las partículas en cualquier sección transversal del cantilever ó de la viga, fig. 1 ó 2) debe ser igual al momento de flexión, M, ó suma algebraica de los momentos de todas las fuerzas externas en cada lado de la sección.

### Reacciones de las fibras.

**6.** En una *armadura* ó viga *armada* (véase Armaduras) la resistencia de cada uno de sus dos cordones se considera obrando en una línea que pasa por los centros de

gravedad de sus secciones transversales; pero, en un cantilever sólido, fig. 1, ó viga, fig. 2, el momento resistente total es la suma de los momentos resistentes separados de las varias fibras de toda la sección transversal.

## Superficie neutra. Eje neutro.

**7.** Cuando un cantilever (ó viga) se cimbra, las fibras en la parte superior (ó inferior) de cada sección transversal se extienden mientras las de la parte inferior (ó superior) se comprimen (véanse figs. 1 y 2); siendo la extensión y la compresión mayores en el borde superior y en el inferior de la sección y decreciendo de all á uniformemente hacia una superficie interior *nn*, figs. (*a*), cerca del centro de la sección transversal. En esta superficie, que se llama la **superficie neutra**, las fibras ni se alargan ni se comprimen. La línea, *oo*, figs. (*b*), formada por la intersección de la superficie neutra con cualquier sección transversal del cantilever ó viga, se llama el **eje neutro** de esa sección.

**8.** A fin de que la suma algebraica de todas las fuerzas horizontales en la sección transversal sea cero, como se requiere para el equilibrio, el eje neutro debe pasar por el centro de gravedad de la sección. En consecuencia, la superficie neutra pasa por los centros de gravedad de todas las secciones transversales.

**9.** El eje neutro puede encontrarse equilibrando la sección (hecha en cartón) sobre el filo de un cuchillo. O véase Centro de gravedad, en Estática, §§ 125, etc. Toda sección tiene un número indefinido de ejes neutros, que pasan todos por el centro de gravedad de ella en otras tantas direcciones diferentes. El eje requerido, en cualquier caso dado, es aquel que es perpendicular al plano del momento de flexión que se estudia.

En la siguiente discusión, suponemos que el eje neutro de la sección es perpendicular á la línea de acción (ordinariamente vertical) del peso; así lo es generalmente.

## Momento de resistencia. Unidad del esfuerzo ó esfuerzo unitario.

**10.** Supónese que el alargamiento ó compresión de cada fibra, y por tanto la resistencia efectivamente ejercida por ella, es proporcional á su distancia vertical sobre ó debajo del eje neutro.

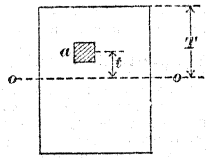

**Fig. 3.**

En la fig. 3, sea

T = la distancia del eje neutro, *oo*, á la fibra más distante, por encima ó por debajo del eje;
S = la tensión por unidad de superficie en dicha fibra más distante (llamada también *tensión unitaria*);
$t$ = la distancia desde el eje neutro hasta cualquier fibra dada;
$s$ = la tensión por unidad de superficie en dicha fibra dada;
$a$ = el área de dicha fibra;
F = el esfuerzo total en dicha fibra;
$r$ = el momento de resistencia de la fibra respecto al eje neutro;
M = momento de flexión en la sección transversal que se considera;
R = momento de resistencia de la sección transversal entera;
$= \Sigma r$ = la suma de los momentos de resistencia de todas las fibras;
I = el momento de inercia de la sección transversal. Véanse §§ 14, etc;
$= \Sigma t^2 a$ = la suma, para todas las fibras, de $t^2 a$;
X = el módulo de la sección (ó momento resistente *) $= \frac{I}{T} = \frac{R}{S}$. Véanse §§ 25, etc.

* *N. del T.* — Entre los ingenieros españoles es más conocido por *momento resistente*.

Entonces el esfuerzo por unidad de superficie en cualquier fibra dada, es $= s = S\frac{t}{T}$; su esfuerzo total, F, es $= as = Sa\frac{t}{T}$; y su momento resistente, $r$, es $= Ft = Sa\frac{t^2}{T}$.

En consecuencia, el momento resistente, R, de la sección entera, es

$$R = M = \Sigma r = \Sigma Sa\frac{t^2}{T} = \frac{S}{T}\Sigma t^2 a = \frac{S}{T}. \quad I.$$

En consecuencia también, $S = MT/I$; $I = MT/S = TX$; $T = SI/M$.

Puesto que $S/s = T/t$, tenemos $S/T = s/t$, y $R = M = SI/T = sI/t = SX$.

**En vigas de sección rectangular,** pág. 491, de ancho, B, y de altura, D, tenemos $I = BD^3/12$; y $T = D/2$. En consecuencia,

$$S = 12MT/BD^3 = 6M/BD^2; \text{ y}$$
$$R = M = SBD^3/12T = SBD^2/6.$$

Cuando se ensayan las resistencias de las vigas hasta su ruptura, el valor alcanzado por S se llama: el **módulo de ruptura.**

**11.** Se notará que las resistencias de vigas semejantes de cualquier forma, y las de vigas rectangulares, sean semejantes ó no, son directamente proporcionales al producto, ancho × cuadrado de altura. Véase § 63.

**12.** Cuando el esfuerzo, S, sobre las fibras extremas, es = al límite de elasticidad del material, el fracaso es inminente. El esfuerzo permitido por unidad de superficie es, como máximo, la mitad del que corresponde al límite de elasticidad, y la carga de seguridad es aquella bajo la cual S no excede de la unidad del esfuerzo permitido.

**13.** La misma cantidad de material que compone una viga sólida, fig. 2, presentaría mayor resistencia á la flexión ó ruptura, si estuviera cortada en dos longitudinalmente á lo largo de la superficie neutra, *nn*, y convertida en cordones superior é inferior de una viga armada; porque, primero, el brazo de palanca con que obra la resistencia se aumenta así considerablemente; y, segundo, las alturas de los cordones son tan pequeñas, comparadas con sus distancias al eje neutro, que puede suponerse que sus fibras obran *unidas* é *igualmente*. En consecuencia, prácticamente, *todas* las fibras en el cordón superior deben ser trituradas ó todas las del inferior desgarradas, *en el mismo instante*, antes de que la viga armada pueda romperse; mientras que, en la viga sólida, las fibras extremas superiores ó inferiores ceden primero; luego las que les siguen y así sucesivamente, unas después de otras.

## Momento de inercia.

**14.** A diferencia del momento de una fuerza, que es el producto de una fuerza y una distancia, el momento de inercia es una cantidad puramente *geométrica*, pues es la suma de los productos de las *áreas* de las fibras por los cuadrados de sus *distansias* al eje neutro. Así, el momento de inercia de una sección dada depende solamente de las dimensiones y forma de esa sección, y es independiente del material y de la abertura que cubre la viga y de la manera cómo está ésta sostenida ó cargada.

**Unidad del momento de inercia.** Siendo el momento de inercia de una figura el producto de un área por el cuadrado de una distancia, su unidad es la cuarta potencia de una unidad de longitud. Así, en un rectángulo de 3 cm de ancho y 4 de alto, $I = \frac{bd^3}{12} = \frac{3 \times 64}{12} = \frac{192}{12} = 16$ cm *cuartos** $= 16$ cm$^4$.

En un rectángulo de 1 cm de ancho y 6 cm de alto, $I = \frac{1 \times 6^3}{12} = 18$ cm$^4$.

**15.** Comparando secciones semejantes de cualquier forma, sus momentos de nercia son proporcionales al producto, ancho × cubo de altura. Compárese § 11.

**16 Los cuadros ilustrados** de las págs. 491 á 493, dan para varias figuras que se emplean con frecuencia:

(1) I = el momento de inercia $= \Sigma t^2 a$;

(2) T = la distancia desde el eje neutro á la fibra más distante;

(3) X = el módulo de la sección ó momento resistente $\frac{I}{T} = \frac{\Sigma t^2 a}{T} = \frac{R}{S} = \frac{M}{S}$;

(4) A = el área de la sección transversal.

---

*N. del T.* — El momento de inercia tiene cuatro dimensiones. Muchos autores llaman a estas unidades del momento de inercia, centímetros *cuartos*, milímetros *cuartos*, etc.; según la unidad que se elija.
